Pre and postvaccination blood specimens had been obtained from 25 of the vaccinated individuals from whom acute and convalescent sera were collected at the time of illness. Fourteen (56 per cent) showed significant rises in titer in the convalescent sera to the J 16 virus but no rise in titer to this strain in the postvaccination sera (Table V). On the other hand, vaccination provoked significant rises in titer to the PR 8 strain, and the antibody levels to PR 8 were only slightly lower in the acute phase sera collected at the time of illness than those present in the postvaccination samples (Table V). The low antibody titers to the closely related J 16 and L 32 influenza virus strains and the relatively high antibody levels to PR 8 in the acute sera of vaccinated individuals together with the significant rise in titers following infection establish the former strains as the etiologic agents of the 1947 influenza outbreak.

DISCUSSION

A year previous to the 1943 influenza A epidemic, Salk and associates¹ inoculated a large number of subjects in a state institution with a combined influenza A and B vaccine similar to one of the preparations employed in this study. The response to the vaccine was good and sera from vaccinated individuals even after a year showed antibody levels several times higher than the prevaccination titers. Proof of the immune state of the vaccinated group after a year compared with the control group was shown in the markedly lower incidence of infection in the former—1.9 per cent compared with 12.4 per cent in the latter. The larger study for the evaluation of influenza vaccines conducted by members and associates of the Commission on Influenza, Army Epidemiological Board, during the 1943 epidemic likewise yielded results significantly in favor of vaccination.^{1, 2} The incidence of infection was 2.2 per cent in the test group and 7.1 per cent among the controls. In this study the inoculations were given immediately before and up to twelve weeks previous to the outbreak of the epidemic. Among the group vaccinated from eight to twelve weeks before the epidemic, however, essentially no protection was shown.¹⁰

The vaccination studies by Francis³ and Hirst⁴ and their associates during the influenza B epidemic of 1945 again yielded favorable results. The vaccinations were carried out within a month preceding the outbreak. Francis and

co workers observed an incidence of 1.15 per cent among the vaccinated and 9.91 per cent among the unvaccinated individuals while Hirst noted an incidence of 0.5 and 12.5 per cent respectively in the test and control groups. The virus strains isolated during the 1943 influenza A and 1945 influenza B epidemics were found to be closely related antigenically to those in the vaccines and the significantly lower incidence among the vaccinated individuals was considered to be due to the prophylactic effect of vaccination.

During the 1947 influenza A epidemic as shown in this and other reported studies, no such dramatic protection following vaccination was observed.^{9, 13} At the University of Michigan Francis Silk and Quilligan¹⁰ reported an incidence of influenza in 10,328 vaccinated individuals of 7.2 per cent compared with 8.1 per cent in 7,615 controls. Likewise in a study at Bucknell University by Fowle and associates, the incidence was 7.05 per cent in vaccinated persons (1,250) and 7.3 per cent in the unvaccinated (794).¹¹ The findings in these studies also support the epidemiological observations made by the Army during the 1947 epidemic among its personnel.⁹ Van Ravenswaay¹³ reported an incidence of 20.2 per cent among 237 vaccinated cadets compared with 27.8 per cent among 284 nonimmunized boys. Siegel and associates¹⁴ studied the 1947 epidemic outbreak among 521 students in a boys' school 88 per cent of whom were vaccinated. Of the vaccinated group 54 per cent were considered to have become ill whereas 49 per cent of the smaller control group contracted influenza. The incidence of moderately ill patients in the vaccinated and unvaccinated groups was 36 and 30 per cent respectively. Weller, Cheever and Enders¹ also found no prophylactic effect following the intradermal inoculation of influenza A and B vaccine during the 1947 epidemic although the antibody response to vaccine by this route appeared to be adequate. The epidemiological data in this study were obtained by questionnaire. Of the 316 individuals who received the vaccine, 34 per cent reported symptoms of acute upper respiratory tract disease, while 28 per cent of 329 unvaccinated personnel had a similar illness during the epidemic period.

The only favorable study reported to date on the value of vaccination against epidemic influenza during 1947 is that of Trimble.¹² This was carried out among the student population at the University of Missouri. The interpretation of the results of this study is open to question because the incidence of influenza among the vaccinated and unvaccinated groups was obtained by polling 'at random various students encountered throughout the University campus and surroundings'. A detailed analysis of the 880 cases admitted to the hospital during the epidemic period would have yielded more definitive results.

In our study the questionnaire method yielded a crude incidence of acute respiratory disease among the vaccinated and unvaccinated groups of 46.5 and 41.5 per cent respectively whereas the incidence during the epidemic period was the same and was only 9.5 per cent in the test and control groups as shown by the clinic data. It was still lower as far as our serologic studies were concerned. Only 38.6 per cent of 148 pairs of sera collected from students showing symptoms of influenza during the epidemic period showed significant rises

(fourfold) in titer to the PR-8 diagnostic antigen. The studies of Sigel and associates¹⁴ employing the complement fixation test and soluble PR-8 antigens¹ showed a much greater number with significant rises.

It is evident from the etiological studies of the influenza epidemic of 1947 that the failure of the combined A and B vaccines to protect was not due to the time interval between vaccination and the outbreak. Vaccination was equally ineffective as reported by others when done from two weeks to two and three months before influenza occurred. Although in our study the interval was from four to five months, antibody determinations on acute sera in vaccinated individuals showed essentially the same high titers as did the sera taken two to three weeks after vaccination. These observations support those of Francis, Salk, and Quilligan¹⁰. In all probability the failure of the vaccine in this epidemic was due, as Francis and associates have pointed out, "to the lack of sufficient antigenic crossing between strains of virus in the vaccine and the prevalent strains responsible for the epidemic." This conclusion was based on evidence obtained from comparative serologic studies with strains isolated during the 1947 epidemic and those incorporated in the vaccines. Our studies on the antigenic relationship between the recently isolated strains and those making up the vaccines support the observations of Francis and associates,¹¹ as well as those of Smadel,⁹ Hirst,¹⁸ and Sigel and co-workers.¹⁹ The failure to demonstrate the usefulness of the vaccine in this epidemic should not be taken as a reflection on the vaccine itself or on previous studies during which positive results were obtained. The vaccination programs of Francis, Salk, Hirst, and other members of the Influenza Commission during the 1943 and 1945 epidemics establish without doubt the value of vaccination as a control procedure against the disease caused by virus strains closely related to those in the vaccine.¹⁵

The low antibody levels against the 1947 strains in the prevaccination and acute sera indicate that the population has had little previous experience with them. Whether the 1947 strains, which were seeded throughout the population during the spring months, will be responsible for subsequent outbreaks cannot be determined. Antibody response to vaccination²⁰ with combined influenza virus A and B vaccines containing, in addition to the PR-8, Weiss, and Lee strains, the FM-1 1947 strain was disappointing. While the PR-8, Weiss, and Lee strains stimulate significant antibody response in individuals with low initial titers (16 to 64) as shown by the chicken red cell agglutination inhibition technique, the FM-1 antigen produced little or no specific antibody rise. These studies point up the fact, as Van Ravenswaay concludes,¹³ that "further study is necessary to define the application and limitations of influenza vaccine as a prophylactic agent." Sigel and co-workers offer suggestions for improving the vaccine.¹⁴ Dingle,²¹ in reviewing the problem of influenza emphasizes the many gaps in our knowledge of this disease and its control.

CONCLUSIONS

No prophylactic effect was observed following vaccination with combined A and B influenza virus vaccines four to five months prior to an outbreak of

influenza among the students at the University of Chicago in March 1947. The time between vaccination and the onset of the epidemic was probably not important in accounting for the lack of effect of the vaccines. Of most importance was the absence of a close antigenic relationship between the viruses in the vaccine and the strains causing the epidemic. This has been demonstrated by virus isolation and serologic studies.

Failure to demonstrate the usefulness of the vaccine during the 1947 epidemic should not be taken as a reflection on the vaccine or on previous studies during which positive results were obtained. Studies made during the 1943 and 1945 epidemics established without doubt the value of vaccination as a control procedure against the disease caused by a virus strain closely related to the strains in the vaccines. However, a comparison of data concerning the value of vaccination during this and the 1943 and 1945 epidemics shows clearly that a vaccine which affords protection during one epidemic does not insure protection against subsequent outbreaks.

The efficiency of a vaccine will depend (1) on its ability to initiate an adequate antibody response and (2) on a close antigenic relationship between the virus components in the vaccine and those initiating the epidemic. Further development of an influenza vaccine of broad antigenic coverage and study of the limitation of its usefulness as a prophylactic agent against epidemic influenza are needed.

TOPICAL APPLICATION OF SUBTILIN TO TUBERCULOUS LESIONS IN MAN*

SEYMOUR M. FARBER, M.D., HENRY R. LAGLE, M.D., HAMILTON H. ANDERSON, M.D., AND RALPH D. GORMAN, M.D.
SAN FRANCISCO, CALIF.

IN RECENT years attention has been focused upon the chemotherapeutic approach to the treatment of tuberculosis. Prominence and its derivatives were found to be highly effective against *Mycobacterium tuberculosis* in vitro and in experimental animals, yet clinical experience failed to reveal demonstrable effects of these drugs on tuberculous infections in human beings. On the other hand streptomycin, which was similarly effective in vitro and in animals has proved efficacious in the treatment of certain phases of human tuberculosis. Final evaluation of an antituberculosis agent must be earned out after its use in the treatment of the disease in human beings.

In the past two years there have been several reports regarding basic investigations of a new antibiotic, subtilin which has been effective against *Mycobacterium tuberculosis* in vitro and to a limited extent in animal experiments. This is a preliminary report on the topical administration of subtilin to eight patients with tuberculous lesions. It is realized that no conclusions can be drawn from a report of this nature, but it was felt that this limited clinical experience should be made available to other investigators.

The antibiotic activity of *Bacillus subtilis* has been recognized for a number of years, and in 1944 subtilin, an antibiotic derived from a strain of *B. subtilis* was announced by Jansen and Hirschmann.¹ Bacteriostatic and bactericidal action in vitro against *Mycobacterium tuberculosis* was reported by Salle and Jann² and confirmed by Wong, Hambly, and Anderson.³ Preliminary studies reported by Salle⁴ indicated that experimental tuberculosis in guinea pigs might be favorably altered by administration of subtilin but experimentation in vivo was retarded by certain physical properties of the drug.

The solubility of subtilin in physiologic saline solution and in human serum is approximately 0.05 per cent, although it is readily soluble in water. As shown by Wilson, Lewis, and Humphreys⁵ subcutaneous or intramuscular injection of strong aqueous solutions into animals produces very low concentrations of the drug in the blood and subtilin precipitates at the site of injection. The saline tissue fluids apparently precipitate the antibiotic, and subsequent absorption of the precipitate is exceedingly slow.

From the University of California Medical Service San Francisco Hospital, San Francisco Department of Public Health and the Division of Pharmacology and Experimental Therapeutics, University of California Medical School.

This work was partially supported by Eli Lilly & Company, Indianapolis, Ind.

Received for publication Mar. 8, 1948.

Part of a cooperative study with the Division of Pharmacology and Experimental Therapeutics, University of California Medical School, San Francisco under the direction of Dr. H. H. Anderson, the Department of Bacteriology, University of California, Los Angeles under the direction of Dr. A. J. Salle and members of the staff of the Western Regional Research Laboratory, Albany.

The drug has not been administered orally because tests *in vitro* have revealed that digestive enzymes destroy a considerable portion of subtilin activity.⁷

Observations on chemical and physical properties of subtilin have been reported by Dimick, Alderton, Lewis, Lightbody and Fevold, and more recently by Lewis.⁸

Since subtilin was relatively insoluble in physiologic saline solution, parenteral administration was considered impractical. Although it is fully realized that aerosol administration alone is by no means a satisfactory method of treatment of tuberculosis, it was felt that useful information might be gained by employing the drug topically, and the present study was undertaken.

Topical application was by the intraoral administration of nebulized solutions of subtilin to eight patients with laryngeal or endobronchial tuberculosis.

OBSERVATIONS IN EIGHT CASES

The patients ranged in age from 18 to 60 years and included members of both sexes. All were observed for at least six weeks prior to subtilin therapy. As shown in Table I, four of the patients had tuberculous laryngitis and one had endobronchial disease. Three other patients had moderately or far advanced pulmonary tuberculosis with cavitation, and one of these had a recent bronchogenic dissemination of disease. These latter three patients were considered to have a conspicuous bronchial factor in their pulmonary disease although lesions were not observed in the main stem bronchi at bronchoscopic examination, and subtilin therapy was directed toward presumed endobronchial lesions in the smaller bronchi.

Method of Administration—At the beginning of the study subtilin* was supplied as a 0.25 per cent solution in 0.45 per cent sterile saline solution. Subsequently the strength of subtilin in the solution was increased and the saline concentration was necessarily decreased (due to the low solubility of subtilin in saline). The daily dose was divided into four to ten portions of 0.5 to 1.0 cubic centimeter. The portion was introduced into a nebulizer† attached to a standard oxygen tank and administered intraorally as described elsewhere.⁹

Later a 1.8 per cent aqueous solution of urea was used as the solvent in place of saline. This isotonic solution produced less tracheal irritation.

Both 4 and 6 per cent solutions of subtilin were administered to one patient.

Dosage—Early in the investigation patients were given 10 mg. of subtilin daily, and the dose was increased gradually in the course of two or three months to at least 90 mg. daily. For a considerable period two patients received 90 mg. daily, four patients, 120 mg. daily, and one patient, 160 mg. daily. One patient received 600 mg. daily for six weeks.

Clinical and Laboratory Studies—In an effort to determine the action and possible toxicity of subtilin, the following laboratory procedures were performed.

*The subtilin used in these studies was supplied by the Western Regional Research Laboratory, Albany, Calif.

†Kindly supplied by Vaponefrin Company, Chicago, Ill.

in addition to complete physical, bronchoscopic, x ray, and fluoroscopic examinations determination of vital capacity, measurement of daily sputum output, urinalysis, complete blood cell count, determination of sedimentation rate and of the concentration of nonprotein nitrogen and sugar in the blood and protein in the serum albumin globulin ratio, heteris index, and cephalin flocculation, bromsulfalein liver function test and phenolsulfonphthalein renal function test.

Acid fast bacilli were cultured from the sputum of all patients with one exception, before therapy. Organisms were subsequently recovered from the sputum of this patient and two years prior to subtilin therapy laryngeal biopsy revealed tuberculosis.

Sensitivity of the tubercle bacilli to the antimicrobial action of subtilin was determined in six cases prior to treatment.

During therapy the following procedures were carried out at weekly intervals: measurement of sputum output, culture and smear of three day sputum concentrate, determination of vital capacity and sedimentation rate, complete blood cell count, and urinalysis. Chemical analyses of blood were repeated at monthly intervals.

The progress of the disease was followed during therapy by means of frequent physical, fluoroscopic, and x ray examinations.

TABLE I. SUBTILIN INHALATION THERAPY. DATA OBTAINED FROM EIGHT PATIENTS

PATIENT	CONDITION	SUBTILIN (TOTAL GM.)	DURATION OF THERAPY (MO.)	IMPROVEMENT
1	Tuberculous laryngitis	3.8	3	Marked
2	Tuberculous laryngitis	51.4	6	Slight
3	Tuberculous laryngitis	17.5	7	Questionable
4	Tuberculous laryngitis	12.0	2½	None
5	Endobronchial tuberculosis	22.8	10	Marked at first reactivation later
6	Presumed endobronchial tuberculosis	6.3	4	None
7	Presumed endobronchial tuberculosis	15.7	6½	None
8	Presumed endobronchial tuberculosis	7.7	4	None

Clinical Observations—

Laryngitis. In the four patients with tuberculous laryngitis, improvement was marked in one, slight in one, and questionable in one. In the fourth the disease progressed and the patient died.

The patient who showed marked improvement (Patient 1, Table I) had moderately advanced pulmonary tuberculosis with cavitation. Prior to subtilin therapy this patient had undergone therapeutic pneumothorax and phrenicectomy. The laryngeal lesions had been treated previously with penicillin inhalation and local application of sulfadiazine crystals in an effort to control secondary infection, and the disease process revealed slight improvement prior to application of subtilin. A large cavity had not responded to pneumothorax. The laryngitis improved rapidly after institution of subtilin therapy and after four months only scarring of the vocal cords remained. No change in the larynx occurred in six months thereafter, although reactivation of pulmonary disease

occurred. Since marked improvement in the laryngeal lesions occurred within one week of the beginning of subtilin therapy and while the dose was only 10 mg daily, the relationship of the antimicrobial therapy to the disease regression is difficult to evaluate.

The patient whose condition showed slight improvement (Patient 2) had active pulmonary disease. After two and a half months of subtilin therapy there was moderate subjective and slight objective improvement. Despite continuation of subtilin therapy for a total of six months, no further improvement occurred.

The patient showing questionable improvement (Patient 3) had advanced pulmonary tuberculosis confined to the right lung. Subtilin inhalations were originally instituted to observe the possible effect on the pulmonary lesions. Despite the development and subsidence of a right pleural effusion during subtilin therapy, the parenchymal disease showed slight gradual healing in x-ray studies. Hoarseness also developed while this patient was being treated, and laryngoscopic examination revealed lesions consistent with tuberculous laryngitis. Symptoms remained mild while use of the drug was continued, but after discontinuance the laryngeal disease showed progression, both subjectively and objectively. Whether this demonstrates any effect of subtilin on the laryngeal lesions is very doubtful.

Patient 4 had advanced pulmonary tuberculosis complicated by very severe and deeply infiltrated tuberculous laryngitis and, as later shown at autopsy, obstructive involvement of the esophagus. The laryngitis progressed during subtilin therapy. The possibility of influencing a process of this nature by topical application of a drug to the larynx is unlikely.

Endobronchial Disease. Therapy in one subject (Patient 5) could be carefully evaluated because of extensive lesions visible at bronchoscopy. Before treatment the left main stem bronchus of this patient was 80 per cent occluded by tuberculous granulations and debris. After three and a half months of subtilin therapy, during which the dose was gradually increased to 30 mg daily, bronchoscopy revealed definite evidence of healing and only 20 per cent occlusion. After eight and a half months of therapy, during which the dose was increased to 120 mg daily, bronchoscopy revealed no occlusion or other evidence of endobronchial disease. During subtilin therapy there was no appreciable change in the far advanced bilateral pulmonary tuberculosis, no increase in vital capacity (900 cc), and no conversion of the positive results of examination of the sputum. After ten months of subtilin therapy, another bronchoscopic examination revealed inflammation and granulations involving pharynx, larynx, trachea, and bronchi. This was interpreted as being tuberculous and recent in origin. Sputum cultures at this time revealed *Myco tuberculosis* organisms which were twice as resistant to subtilin as organisms recovered in this case before treatment. It seems possible that subtilin favorably influenced the endobronchial disease originally, but it had no demonstrable effect on the pulmonary parenchymal disease. Although the development of marked bacterial resistance to subtilin was suspected, this was not proved by cultural studies, and the cause of the reactivation of endobronchial disease is unknown.

The condition in the three patients in whom endobronchial tuberculosis was presumed to be present in the small bronchi (Patients 6, 7 and 8) showed no significant change during subtilin therapy. In the absence of visible endobronchial lesions, evaluation of therapy was based on clinical condition and roentgenographic change in parenchymal disease. While there was no radiologic evidence of improvement in the extensive pulmonary disease, progression of parenchymal lesions was not demonstrated. In the patient in whom bronchogenic dissemination had occurred (Patient 8) the disease had been progressive at the beginning of administration of subtilin.

Laboratory Studies—Strains of *Mycobacterium tuberculosis* isolated from six of the eight patients prior to therapy showed no growth in subtilin dilutions of 1:400,000 (Patients 5, 6 and 8), 1:200,000 (Patients 3 and 7) and 1:100,000 (Patient 1)*. After three and a half months of therapy the organisms isolated from three of these six patients (Patients 6, 7 and 8) showed no growth in solutions of subtilin four times the original effective concentrations. This decrease in bacterial sensitivity is probably beyond the experimental error of the procedure and is considered suggestive evidence of the development of bacterial resistance to subtilin *in vivo*. In one subject (Patient 5) only a twofold decrease in sensitivity was demonstrable after eight and a half months of therapy. This change may be within the experimental error of the test.

Determination of the concentration of subtilin in the blood was carried out in a patient who had received the drug by inhalation for three months in the last two weeks of which the dose had been 400 mg. daily. No subtilin activity could be demonstrated in the blood.¹⁰

Toxicity—No evidence of toxicity in the kidneys, liver or bone marrow was encountered.

Administration of subtilin by inhalation was associated with irritation of the respiratory tree in almost all patients. Mild dyspnea, increase in cough and sputum, and mild pharyngitis occurred commonly during the first two or three weeks, after which the symptoms subsided or disappeared. The dyspnea and cough were frequently relieved by including from 2 to 4 drops of 0.25 per cent aqueous solution of Neosynephrin hydrochloride in the nebulized solution. Frank wheezing and sibilant rales were not associated with this reaction. In one case recurrent hemoptysis was encountered and in several others isolated episodes occurred.

Recurrent headaches developed in one patient receiving subtilin and there were several isolated instances of headache among the patients receiving the drug. No neurologic abnormalities were found and when headache was encountered it responded to the usual medications. Implication of subtilin as a causative agent does not seem warranted.

Asthma developed in one subject (Patient 1) after three months of therapy and it was necessary to discontinue administration of the drug for this reason. No other evidence of hypersensitivity was observed.

It should be emphasized that the lack of serious toxicity encountered in the clinical use of this drug may be inherent in the mode of administration which results in negligible systemic absorption of subtilin.

*We are indebted to Miss Joyce Amlexen for these studies.

COMMENT

It is fully realized that a drug should be administered systemically in order to exert a significant bacteriostatic or bactericidal effect in a disease such as tuberculosis in man. It is also fully appreciated that a large number of patients should be treated before any definite statement can be made regarding the clinical value of an antituberculosis agent. This preliminary investigation of the topical application of subtilin in a small number of cases does not warrant drawing any conclusions. However, suggestive evidence of therapeutic activity and of minimal toxicity affords stimulus for continued research.

Basic investigation is being directed toward the development of a modification of subtilin that can be administered parenterally. Intravenous infusion of very dilute solutions is possible in animals,¹¹ but utilization of this technique in man for a prolonged period would be impractical. The development of derivatives of subtilin with increased solubility in physiologic fluids and with retention of potency is being investigated by Lewis and associates. Preliminary results with some of these derivatives are encouraging. Work is also being carried on by MacLay and others regarding the possibility of combining subtilin with pectin to alter its characteristics of absorption.

Further investigation of the therapeutic possibilities of subtilin must await basic research directed toward development of derivatives more soluble in physiologic fluids. Subtilin in its present form has no place in the treatment of tuberculosis other than for purely investigative purposes.

ADMINISTRATION OF PENICILLIN AND STREPTOMYCIN BY MEANS OF THE HYPOSPRAY APPARATUS (JET INJECTION) ABSORPTION, TOXICITY AND STABILITY

HAROLD L. HINSH, M.D., HENRY WELCH, Ph.D., BERNARD MILLOFF, M.D.
AND SOL KATZ, M.D.
WASHINGTON, D. C.

RECENTLY a device for the parenteral administration of solutions or suspensions of drugs known as the Microjet or Hypospray became available for study. Preliminary reports on its use clinically have been published by Hingson and Hughes¹ and by Hingson and associates. The principle of the instrument is based upon the fact that an extremely fine high pressure jet is capable of piercing the human skin with at most only slight pain. The instrument injects the drug in solution or suspension by means of high pressure* obtained through the release by means of a button of a previously wound calibrated high tension spring which is attached to a plunger. The material to be injected is placed in a metal ampule (Metapule). It has a capacity of 0.25 cc and is shaped like a blunt nosed bullet with an orifice 0.003 inch in diameter in the rounded tip while the butt end is stoppered with a rubber plug. The tip of the Metapule is held against the skin at the site of the injection with the base locked securely in the apparatus. The plunger explodes against this rubber stopper which forces the material out of the Metapule and through the skin as a fine spray. The material is deposited subcutaneously and intramuscularly to depths varying from 0.2 to 2 cm depending on the tension of the spring and the site of injection¹. Since the orifice in the Metapule through which the medication is expelled is only 0.003 inch the size of a human hair pain is either nonexistent or very slight because there is little trauma to the tissues and a minimum of pain nerve fibers is stimulated. These factors are discussed in detail elsewhere¹. Another advantage attributed to this instrument is that it eliminates the fear incident to injection by needle and syringe.

ABSORPTION

Since many infections amenable to penicillin and streptomycin therapy require injections at regular intervals throughout the day the availability of this instrument for the administration of these antibiotics would considerably facilitate therapy. A study of the absorption of penicillin and streptomycin following intramuscular injection was undertaken. Doses of 50,000, 100,000 and 200,000 units of penicillin and of 0.05 and 0.1 Gm of streptomycin were employed. The latter dose of both antibiotics was found to be the maximum amount of each drug that could be dissolved in 0.25 cc of solution (the capacity of a Metapule).

*From the Georgetown Medical Division, Gallinger Municipal Hospital, the Department of Medicine, Georgetown University School of Medicine and the Division of Penicillin Control and Immunology, Food and Drug Administration, Federal Security Agency.

Received for publication April 13, 1948.

The theoretical pressure in the Metapule is about 4 kg per square centimeter. This is proportional however to the much smaller pressure of 11 Gm exerted on the fine jet or column of liquid in the orifice of the Metapule. The jet or column exerts a pressure varying from 300 to 3,500 pounds per square inch on the skin through which it makes a minute hole or channel.

The percentage of patients having assayable concentrations of penicillin in the blood following the injection of 50,000, 100,000, and 200,000 units of penicillin by means of the Hypospray is shown in Table I. Following the injection of 50,000 units, detectable concentrations in the blood were found in all of the patients at one hour and in 94 per cent at two hours. Measurable blood concentrations were found in only 63 per cent of the patients at the third hour and

TABLE I PERCENTAGE OF PATIENTS WITH MEASURABLE CONCENTRATIONS IN THE BLOOD FOLLOWING THE INJECTION OF VARIOUS DOSES OF BUFFERED CRYSTALLINE SODIUM PENICILLIN G BY MEANS OF THE HYPOSPRAY APPARATUS

200,000				100	86	14

in 31 per cent at the fourth hour after injection. When 100,000 units were administered, assayable concentrations were detected in the blood of all patients at four hours, in 50 per cent at six hours, and in none of the patients at eight hours after administration. Of the patients who were given 200,000 units of penicillin by this method, measurable concentrations were demonstrated in the blood of all the patients at four hours and in 86 per cent six hours after injection. After eight hours only 14 per cent of the patients were found to have demonstrable penicillin concentrations in the blood.

In order to compare the height and duration of the concentration of penicillin in the blood following administration by the Hypospray with that by the

needle and syringe 50,000 units were given to a group of patients by both methods, and blood for penicillin assay was taken two three and four hours thereafter. The volume of the penicillin solution was 15 cc when given by needle and syringe and 0.25 cc when the Hypospray was employed. It can be seen from Table II that the concentrations obtained with the Hypospray were somewhat higher and more prolonged than those obtained with the use of the needle and syringe. Although the volumes of the solution injection were not the same, it is believed that that does not account for the differences. It is our opinion that the differences may be due to the fact that part of the penicillin injected with the Hypospray is deposited subcutaneously. It has been demonstrated that the concentrations of penicillin in the blood are prolonged following subcutaneous injection as compared with the other methods of parenteral injection.

TABLE III. AVERAGE CONCENTRATIONS OF STREPTOMYCIN IN THE BLOOD FOLLOWING THE INJECTION OF VARIOUS DOSES OF STREPTOMYCIN BY MEANS OF THE HYPOSPRAY APPARATUS

DOSE (GM)	AVERAGE CONCENTRATION IN THE BLOOD ($\mu\text{G}/\text{CC}$)		
	HOUR		
	4	8	12
0.05	1.25	0.62	0.31
0.1	2.5	1.25	0.62

The mean concentrations of streptomycin in the blood at four eight and twelve hours following the injection of 0.05 and 0.1 Gm of streptomycin are shown in Table III. At four, eight and twelve hours after the administration of 0.05 Gm of streptomycin the mean concentrations were 1.25, 0.62 and 0.31 μg per cubic centimeter of serum respectively. Following the injection of 0.1 Gm the mean concentrations were 2.5, 1.25 and 0.625 μg per cubic centimeter of serum at the same times.

3	3	6	1.25	6	6	3	6	3
4	2.5	2.5	2.5	3.0	1.25	1.25	5.0	2.5

Since significant concentrations were obtained twelve hours following the injection of 0.1 Gm of streptomycin it was decided to investigate the results of repeated injections of this dose at twelve hour intervals and also to compare these results with the same dose given by needle and syringe. For this study,

blood for streptomycin assay was taken every twelve hours, immediately before the next injection (twelve hours following the preceding injection), over a period of four days. It can be seen from Table IV that there was no added effect from repeated injections and that the concentrations in the blood at the twelfth hour were at a plateau. Furthermore there was essentially no difference in the results obtained with the two methods of administration. Several patients were given 0.1 Gm. of streptomycin every four hours five times a day by means of the Hypospray. Assay of the blood at the fourth hour (immediately before the next injection) revealed constant concentrations at that hour, indicating no increment of streptomycin in the blood as a result of repeated injections.

The instrument employed in these studies had a spring which when released exerted a static pressure of 2,300 pounds per square inch on the skin. Although it has been shown that the depth and spread of the injected material varies with the site of injection and the race of the patient,¹ no differences in the blood concentrations of these antibiotics were noted in our series despite the fact that the sites of injection were varied (flexor and extensor aspects of arms, thighs, and buttocks) and both white and Negro patients were studied.

TOXICITY

Most patients complained of momentary stinging at the site of injection particularly with the larger doses of penicillin and streptomycin. Of the sixty patients injected in this series, only four have shown an unfavorable reaction. One patient developed a small area of induration at the site of injection after twenty-four hours. This abated after twenty-four hours following treatment with warm, wet dressings. Two patients developed small hematomata at the sites of injection. A fourth patient developed a small, subcutaneous nodule at the site of injection several days after administration. This persisted for a period of two weeks. Similar reactions have been reported by others.² Although it is relatively simple to master the technique of administration with the Hypospray, small linear cuts, blister formation, and bleeding were obtained as the result of improper handling during the early use of this instrument. The area prepared for injection should be allowed to dry before administration is attempted in order to prevent the instrument from slipping on the skin.

One patient with tuberculosis was treated with five injections per day of 0.1 Gm. streptomycin every four hours. The posterior aspects of the arms and thighs were rotated as the site of injection. After about ten days of therapy, small nodules developed at the site of injection within twenty-four hours after each injection. It is believed that these reactions were the result of repeated subcutaneous depositions of part of the streptomycin during administration with the Hypospray apparatus. In support of this are the results of absorptory studies, reported herein, which indicate that some of the drug was deposited subcutaneously.

There is also evidence to indicate that the high concentrations or both streptomycin and penicillin may have been a factor in the development of the few untoward local reactions observed with the use of the Hypospray in this series.

These studies were for the most part carried out on patients with tuberculosis. After the first few patients had received injections by this instrument there was no problem in securing volunteers for the study in spite of the fact that several blood specimens were to be taken from each patient. This indeed testifies to the efficiency of this device particularly when the attitude of these patients is considered.

STABILITY

Our data on the stability of several aqueous solutions of penicillin stored in Metapules and employed in these studies are shown in Table V. The instability of penicillin in aqueous solution is well established. These results indicate that the stability of aqueous solutions of penicillin stored in Metapules remains undependable. The apparent discrepancy in some of the results shown in Table V is undoubtedly explained by the facts that the hand method of filling the Metapules and the method of assay are subject to error.

TABLE V. STABILITY OF SOLUTIONS OF BUFFERED CRYSTALLINE SODIUM PENICILLIN G DISPENSED IN METAPULES (0.25 CC CAPACITY) EMPLOYED IN ADMINISTERING DRUGS BY MEANS OF THE HYPOSPRAY APPARATUS

†Refrigerated.

COMMENT

Hinason and associates have demonstrated that gonorrhea can be treated as effectively with this apparatus as with needle and syringe. Dispensing penicillin in solution in Metapules at present for general commercial use with the present design of the apparatus is at least very impractical. With the available instrument the dose of the antibiotics is limited by the size of the Metapule. This method of administration is not feasible particularly in the treatment of infections requiring large doses of streptomycin. It appears, however, that the problem of dispensing penicillin and streptomycin will be solved.³ The instrument has been improved so that it will discharge the contents of 0.5 and 1 cc Metapules.

The possibility of drugs being deposited in blood vessels during the course of injection with the Hypospray was anticipated. In spite of deliberate efforts to deposit some of the drugs injected directly into blood vessels, this has been accomplished only once when injection was made directly over a vein.³ With most drugs this would be relatively unimportant but there are some drugs which would have serious consequences following injection directly into the circulation. Further investigation is necessary to resolve this problem completely.

SUMMARY

These studies are evidence that penicillin can be administered by means of the Hypospray apparatus. Furthermore the device has the advantage of decreasing the pain and fear of injection which attend available methods. There are several problems to be solved before the device can be used generally in clinical practice.

We wish to thank Dr. William A. Randall and Dr. Clifford V. Price and Miss Velma L. Chandler for their assistance in the conduct of these studies.

THE USE OF YEAST PHASE ANTIGENS IN A COMPLEMENT FIXATION TEST FOR HISTOPLASMOSIS

I PRELIMINARY RESULTS WITH RABBIT SERA

SAMUEL SASLAW, M.D., PH.D.* AND CHARLOTTE CAMPBELL
WASHINGTON, D. C.

THE coincidence of pulmonary calcifications and skin sensitivity to histoplasmin¹ has suggested either a higher rate of infection with *Histoplasma capsulatum* than previously recognized or infection with an immunologically cross reacting antigen. A recent report² that *H. capsulatum* had been isolated from nonfatal cases implies that infection with this agent may not be uniformly fatal. The high prevalence of skin sensitive reactors to histoplasmin in the eastern central states warrants the search for additional tools for evaluating evidence of past or present infections with *H. capsulatum*. Immunologic procedures properly developed and controlled may offer additional information.

Skin test antigens (histoplasmin) are prepared from broth filtrates of the mycelial phase of *H. capsulatum*. Since it is the yeast phase of the organism that appears in affected tissues of man and animal studies utilizing this phase of the infectious agent may yield additional and possibly more specific results. The ready growth and maintenance of *H. capsulatum* in the yeast phase has been reported previously by one of us (C.C.C.) and by others³⁻⁵. The utilization of this antigen in preliminary complement fixation studies in experimental animals is herein described. Both viable and nonviable antigens were used in immunization. Since no appreciable differences were noted other than a slightly greater immunogenic capacity of the viable forms the experiments described below are those utilizing killed antigens.

MATERIALS AND METHODS

Antigens.—Three strains of *H. capsulatum* in the yeast phase which we call G 2, G 5 and G 6 were used†. Two strains of *Blastomyces dermatitidis* (A 1 and A 5) one strain of *Blastomyces brasiliensis* (B 2) and AMS E 11 strain of *Candida albicans* were also studied‡. All of the cultures were grown in the yeast phase on glucose cystine agar slants at 37° C. for five to fifteen days. The growth was washed off with sterile buffered saline and the pooled washings were filtered through sterile gauze placed in a sterile rubber stoppered vial and heated at 56° C. for four hours. This constituted the stock antigen. For each series of tests calculated amounts of this stock suspension were withdrawn, washed

Received for publication March 31, 1948.

First Lieutenant Medical Corps, Army of the United States.

†The G 2, G 5 and G 6 strains of *H. capsulatum* were reverted from the mycelial phase of strains 71, 90, and 60 respectively from the collection of Dr. N. F. Conant at Duke University.

‡A 1 strain of *B. dermatitidis* and A (Duke 930) and B strain of *B. brasiliensis* (Duke 871B) are all isolates from human subjects received from Dr. Conant at Duke University. The E 11 strain of *C. albicans* was isolated from a patient at the Army Medical Center.

two times with buffered saline, and diluted for use. The optimal antigen dilution was then determined by titration as that amount which gave the highest titer with homologous antigen and was not hemolytic or anticomplementary. The stock antigen retains its titer for several weeks when stored in the refrigerator. The portions removed for the daily test were heated at 56° C for thirty minutes to eliminate any possible anticomplementary activity.

Preparation of Sera—Young, healthy, albino rabbits weighing 5 to 7 pound were immunized with yeast phase antigens of *H. capsulatum* in the following manner. The organisms grown on cystine agar slants for five days at 37° C were washed off with 0.5 per cent formalized isotonic saline and stored overnight at 3 to 4° C. The suspensions were then washed three times with physiologic saline and resuspended in 0.1 per cent formalized saline to a turbidity equal to the No. 3 MacFarland nephelometer standard. Rabbits were injected intravenously for six successive days with the following amounts: 0.1, 0.2, 0.5, 1.0, 2.0, and 2.0 milliliters. Booster injections of 2 ml were given one and two weeks after the last injection and the rabbits were bled six days after the last booster. The same procedure was used for the production of sera against the antigens of the other organisms used in this study.

Complement Fixation Test—The complement fixation test of Kent and Rein,¹⁰ developed at the Army Medical School, was employed in these studies.

Diluent For all dilutions 0.85 per cent salt solution buffered to pH 7.3 with 0.005M phosphate was employed.

Sheep's Red Blood Cells A suspension of 2 per cent washed packed cells was prepared from blood collected aseptically into an equal volume of modified Alsever's solution.¹¹

Hemolysin Hemolysin prepared by the immunization of rabbits was used in an optimal dilution beyond which further decrease in dilution failed to diminish the quantity of complement required for fifty per cent hemolysis.¹² An equal volume of this optimally diluted hemolysin was poured into the cell suspension and mixed by ten successive pourings and at least ten minutes at room temperature were allowed for sensitization.

Complement Lyophilized commercial guinea pig serum, 7.0 ml, was rehydrated with 5.0 ml of the accompanying preservative containing 2 per cent boric acid and 5 per cent sodium acetate. A stock 1:20 dilution was prepared by adding 19 parts of salt solution to 1 part of rehydrated serum. The complement was titrated by the method of Kent, Bulant, and Rein¹³ for the determination of the 50 per cent unit of complement, and 3 units were employed in the test.

TABLE I. COMPLEMENT FIXATION TEST FOR HISTOPLASMOSIS

	TEST		REAGENT CONTROLS		
	WITH ANTIGEN	SERUM CONTROL	ANTIGEN	COMPLEMENT	SENSITIZED CELLS
Serum dilutions (ml)	0.2	0.2			
Complement (ml) (3 units)	0.2	0.2	0.2	0.2	
Antigen (ml)	0.2		0.2		0.6
Salt solution (ml)		0.2	0.2	0.4	
<i>Fixation overnight at 36° C</i>					
Sensitized cells (ml)	0.4	0.4	0.4	0.4	0.4
<i>Incubation for thirty minutes at 37° C</i>					

Degrees of reaction in tests are read according to the percentage of cells remaining unhemolyzed. The tube with the greatest dilution of serum showing 50 per cent or less of hemolysis represents the titer of the serum. It is recommended that color standards representing 0, 10, 20, 30, 40, 50, 60, 70, 80, 90, and 100 per cent hemolysis be employed to assist in determining the aforementioned grades of reaction.

Test The test was conducted with suitable controls as indicated in Table I. The reagents were added in the order given and the tubes thoroughly mixed. The tubes were then placed in the refrigerator at 3 to 6° C overnight. Sheep's cells sensitized at least ten minutes previously were then added, the tubes were shaken and incubated in a 37° C water bath for thirty minutes. The tubes were then centrifuged at 7,000 revolutions per minute.

for five minutes and the tests were read against a diffuse source of light in terms of per cent hemolysis using control standard tubes for comparison. The greatest serum dilutions showing 50 per cent or less of hemolysis represent the titer of the complement fixing antibodies.

RESULTS

Experiment 1, Titration of Antigen—Each lot of antigen was titrated to determine the optimal dilution. The antigenic unit was considered to be the greatest concentration contained in 0.2 ml. beyond which further increase failed to enhance appreciably the serum reaction. It was required that the optimal concentration be neither hemolytic nor anticomplementary. It was found that the optimal dilution usually lay between 1:20 and 1:50 of the stock solution depending on the concentration of the latter. Table II demonstrates the determination of the optimal antigen dilution of the G 2 antigen. The tubes containing the 1:40 dilution of antigen showed no traces of anticomplementary activity and likewise reacted with the antiserum to give clean cut fixation of complement. The next dilution of antigen (1:53.3) reacted even more favorably. Thus an intermediate dilution of 1:50 was selected arbitrarily as the optimal amount and was used in subsequent studies.

TABLE II. DETERMINATION OF THE OPTIMAL DILUTION OF ANTIGEN USING THE G 2 STRAIN OF *H. CAPSULATUM* AND SERUM PREPARED IN RABBITS AGAINST G 2

DILUTION OF ANTIGEN (0.2 ml.)	POSITIVE SERUM DILUTIONS IN PER CENT (0.2 ml.)					CONTROLS (%)		
	1:10	1:20	1:40	1:80	1:160	ANTIGEN	COMPLEMENT	CELLS
1:10	0	0	0	10	95	97	100	0
1:13.3	0	0	0	25	95	97		
1:20	0	0	0	25	95	97		
1:26.6	0	0	0	30	95	97		
1:40*	0	0	0	35	95	100		
1:53.3*	0	0	0	20	60	100		
1:80	0	0	0	30	90	100		
Serum control	100	100	100	100	100			

0 No hemolysis 100 complete hemolysis

*Optimal dilution lies between 1:40 and 1:53.3 since there is good fixation but no trace of anticomplementary activity. For tests 1:50 was employed.

Experiment 2—Three sets of rabbit antisera prepared against three strains of *H. capsulatum* (G 2, G 5, G 6) were titrated against homologous and heterologous strains of these organisms as well as against yeast phase antigens of two strains of *B. dermatitidis* and one of *B. brasiliensis*. Fixation of complement was obtained in relatively similar titers with all combinations of histoplasma yeast phase antigens and histoplasma antisera. For example as noted in Table III sera prepared against G 2 histoplasma antigen fixed complement in the presence of its specific antigen to a titer of 1:160. In the presence of the G 2 antigen G 5 and G 6 antisera bound complement in dilutions of 1:80. Sera prepared against *C. albicans* yeast phase *Sporotrichum schenckii**¹⁴ and *Cryptococcus neoformans** gave negative complement fixation results in the presence of the histoplasma G 2 antigen, while *B. dermatitidis* serum fixed complement only in dilutions up to 1:10.

0 No hemolysis (complete fixation) 100 complete hemolysis (no fixation)

The titer was taken as being the highest dilution of serum showing 50 per cent or less of hemolysis

When the G-5 antigen was used (Table IV), G-2, G 5, and G 6 antisera fixed complement in dilutions of 1 160, 1 80, and 1 80 respectively. Again no fixation was noted with sera prepared against the other fungi studied with the exception of *B. dermatitidis* serum which fixed complement in low titer. Similar results were obtained using G-6 antigen and homologous and heterologous sera.

TABLE IV REACTIONS IN THE COMPLEMENT FIXATION TEST EMPLOYING AN OPTIMAL DILUTION OF THE G 5 STRAIN OF *H. CAPSULATUM* AS ANTIGEN AND THE SAME SERA USED IN TABLE III

See footnotes to Table III

Experiment 3—Strains of blastomyces and histoplasma have been found to cross react in the skin testing of animals infected with these agents¹⁰ as well as in complement fixation tests employing mycelial phase histoplasma and blastomycem as antigens.^{6, 10} In Experiment 2 it was noted that blastomycem antiserum in low dilution fixed complement in the presence of yeast phase antigens of *H. capsulatum*. In order more fully to evaluate this possible relationship, complement fixation tests were done employing yeast phase blastomycem antigens in the presence of blastomyces and histoplasma antisera.

In our hands the immunogenic capacity of *B. dermatitidis* in rabbits has been far inferior to that of *H. capsulatum*. Despite repeated booster injections the highest titer of complement fixing antibodies was 1:40. When the A 5 antigen of *B. dermatitidis* was employed (Table V) in contrast to the 1:40 titers of the blastomyces antisera the G 2, G 5 and G 6 histoplasma antisera fixed complement at dilutions of 1:80, 1:80 and 1:20 respectively. At first glance it would appear that the results obtained using blastomyces antigen show cross reactions too great to allow proper evaluation. However when the titers of the histoplasma antisera against the blastomyces antigen are evaluated in terms of their specific titer (compare Tables III and IV with Table V) it will be seen that the nonspecific titers are usually one fourth to one half of the specific titers, whereas the 1:40 titer obtained with blastomyces serum against its specific antigen actually represents maximum titer. Nevertheless the specificity of the

TABLE V. CROSS REACTIONS IN THE COMPLEMENT FIXATION TEST EMPLOYING THE A 5 STRAIN OF *B. DERMATITIDIS* AS ANTIGEN AND SERA OF RABBITS ISOGLUTED WITH THE A 1 AND A 5 BLASTOMYCES ANTIGENS AND THE G 2, G 5 AND G 6 HISTOPLASMA ANTIGENS

complement fixation test using histoplasma antigen in Experiment 2 was greater than that in which blastomyces antigen was used. This type of cross reaction suggests the presence of a common antigenic component shared by *H. capsulatum* and *B. dermatitidis* in which diluted histoplasma antiserum is capable of reacting with the histoplasma antigen carried by both organisms but in which blastomyces antiserum will not react as readily with histoplasma antigen. This may be due to differences in location of the common antigen in the respective antigenic patterns of *H. capsulatum* and *B. dermatitidis* and/or a greater immune response in experimentally infected animals to the former agent as shown by the greater immune response of rabbits to histoplasma antigen.

Experiment 1—In the course of this study a report by Salvin¹⁷ appeared describing the use of a yeast phase antigen of *H. capsulatum* in the Bengston complement fixation test.¹⁸ No cross reactions between *H. capsulatum* and *B. dermatitidis* were noted, and details concerning titers or degrees of fixation were lacking. Since our technique differs in several fundamental respects from these methods *H. capsulatum* and *B. dermatitidis* antigens were prepared according to Salvin's method and a comparison was made of the two types of complement fixation tests.

Table VI shows the results obtained when the complement fixation was done using Salvin's method in its entirety except that hemolysis was read in per cent. Using the G 2 histoplasma antigen and designating complete hemolysis

sis as the end point, titers of 1 160 were obtained with all three strains of histoplasma antiserum, while the blastomyces antisera against the A 1 and A 5 strains both yielded titers of 1 40. The degrees of hemolysis, however, between two-fold dilutions did not vary appreciably. This was particularly true with the G-5, G 6, A-1, and A-5 antisera where the hemolytic range was limited between 90 and 100 per cent. Two factors probably are involved in this type of reaction (1) excess of complement, two full units used in this test represent approximately 5 1 50 per cent units as calculated by means of the Von Krogh alternation formula¹⁹ taking a mean value of 0 175 for the constant $1/n$, this represents almost double the amount of complement used in our test (3 50 per cent units), (2) incomplete fixation at the short one-hour incubation period.

TABLE VII COMPARATIVE EFFECTS OF THE INCUBATION PERIOD ON COMPLEMENT FIXATION, SET A INCUBATED AT 37° C FOR ONE HOUR, SET B INCUBATED OVERNIGHT AT 3 TO 6° C, G 6 ANTIGEN USED IN BOTH SETS

See footnotes to Table III

To evaluate further the second factor, that is the incubation period, two parallel series, A and B, were set up using the G 6 antigen and G 2, G 5, G 6 A-1, and A-5 antisera in the manner used routinely in our test. As noted in Table VII, fixation of set A was carried out at 37° C for one hour while set B was incubated overnight at 3 to 6° C. Definitely stronger and more clear cut fixation was obtained in the set incubated in the refrigerator overnight.

DISCUSSION

The development and use of a stable specific yeast phase antigen of *H. capsulatum* in complement fixation studies using immune rabbit sera is herein

described. Rabbits immunized with yeast phase *H. capsulatum* antigens developed complement fixing antibodies in high titer reacting with homologous and heterologous strains of histoplasma. No fixation occurred when antisera against *C. albicans*, *C. neoformans*, *S. schenckii*, and *B. brasiliensis* were used. However, antisera against *B. dermatitidis* having a specific titer of 1:40 fixed complement in the presence of histoplasma antigens in low dilutions of serum. When blastomyces antigens were used, however, the cross reactions observed to exist only in the smaller dilutions between histoplasma and blastomyces antisera were more pronounced. In fact, because of the weaker immunizing capacity of the blastomyces antigen as compared with the histoplasma antigen, comparable or even higher titers were observed with the histoplasma antisera. However, these titers of histoplasma antisera against blastomyces antigen were usually one fourth to one half of the titer obtained when histoplasma antigen was used. For example, histoplasma sera with a titer of 1:160 fixed complement in the presence of the blastomyces antigen up to dilutions of 1:40. Although numerically this was equivalent to the 1:40 titer of the specific blastomyces antisera, the latter represented the maximum specific titer obtainable under the conditions of our test. This suggests the presence of a common cross reacting antigen in both *B. dermatitidis* and *H. capsulatum* which confirms the observations made on the basis of skin tests in infected animals by Howell¹ and in complement fixation tests by Tenenbein² and Howell³ and Bunnell and Furcolow⁴ in which filtrates of the mycelial phase of histoplasma and blastomyces were used as antigens. The results of the complement fixation tests can be more accurately evaluated by the joint use of properly prepared *H. capsulatum* and *B. dermatitidis* antigens and serial dilutions of the test sera.

The yeast phase antigen of *H. capsulatum* adapts itself readily to use in the complement fixation test of Kent and Rem¹⁰ in which excess of complement is avoided, adequate fixation is allowed and the per cent hemolysis is utilized to obtain clear cut, specific results. We were unable to confirm Salvin's findings that no cross exists between *H. capsulatum* and *B. dermatitidis* in the yeast phase either by use of the Bengtson complement fixation test¹⁷ or by that employed in this laboratory. Our observations are more in accord with others^{5, 15, 16} that immunologic cross reactions between these two agents do exist. This would imply that in complement fixation tests for either human histoplasmosis or blastomycosis both antigens should be employed.

SUMMARY

A method employing yeast phase antigens of *H. capsulatum* in complement fixation tests with immune rabbit sera is described.

The Kent and Rem complement fixation test utilizing per cent hemolysis was clear cut and definite.

An immunologic relationship between *H. capsulatum* and *B. dermatitidis* was demonstrated.

The potential value of employing yeast phase antigens in complement fixation tests for the diagnosis of past or present infections with histoplasmosis

as a possible adjunct to the present methods now available is open to investigation

The authors wish to acknowledge the advice generously offered by Mr John Kent of the Department of Serology, Army Medical Department Research and Graduate School. They are also indebted to Miss Hilarie Boyd for the preparation of complement and amboceptor, and to Miss Sylvia Cury for technical assistance.

THE CONCENTRATION OF THE LABILE FACTOR OF THE PROTHROMBIN COMPLEX IN HUMAN, DOG, AND RABBIT BLOOD ITS SIGNIFICANCE IN THE DETERMINATION OF PROTHROMBIN ACTIVITY

ARMAND J. QUICK, M.D., PH.D., AND MARIO STEFANINI * M.Sc., M.D.
MILWAUKEE, WIS.

THE prothrombin time, which may be defined as the coagulation time of plasma to which an excess of thromboplastin has been added is generally accepted as a reliable quantitative measure of prothrombin activity. Until recently prothrombin was considered a unitary substance and any diminution of prothrombin activity was interpreted as a specific decrease of this clotting agent. In 1943 one of us (A. J. Q.) found that the loss of prothrombin activity in stored plasma was not due to a diminution of the classic prothrombin which is adsorbable by $Al(OH)_3$ and which diminishes in dicumarol poisoning but to that of a new factor not previously recognized.¹ This substance was named component A of prothrombin but when it was later found that the adsorbable fraction of prothrombin contained two components, the terms components A and B were applied to these and the substance which disappears in stored plasma was redesignated the labile factor.

Soon after these studies were published Owren² independently discovered a similar clotting agent which he named factor V. He found that this factor was lacking in a patient with a serious hemorrhagic diathesis. In retrospect it seems probable that the patient of Rhoads and Fitz Hugh³ diagnosed as having idiopathic hypoprothrombinemia, likewise suffered from a lack of the labile factor. Since diminution of this agent causes marked impairment of coagulation and a concomitant bleeding condition it seems obvious that the labile factor is indispensable for coagulation or more specifically for prothrombin activity.

It becomes of great practical importance to know how this new factor affects the prothrombin determination. In this study therefore an attempt has been made to obtain information on that question. So far no means have been found to alter the concentration of this agent in vivo and clinical study too is limited since Owren's case is the only one known at present in which the factor appeared diminished. Stored plasma from which the labile factor has been markedly reduced is the only available means for the assay of the substance in various types of plasma and for studying quantitatively its effect on the prothrombin time. Since human blood contains a relatively low concentration of the labile factor storage will bring about a prompt and striking depletion

and therefore aged oxalated human plasma was found satisfactory for the present studies. Storage of plasma in open test tubes at ordinary refrigerator temperatures (4°C) for seven days usually resulted in an increase of the prothrombin time from a normal of 12 seconds to 40 or more. No attempt was made to isolate the labile factor since it was not considered essential for the objective of the present study. By treating the plasma to be assayed with tricalcium phosphate, both components A and B are removed, thus leaving, as the only known plasma constituents playing a role in the process of clotting, fibrinogen and the labile factor.

MATERIAL AND METHODS

The Concentration of the Labile Factor in Human, Dog, and Rabbit Plasma—To assay blood for its content of labile factor, it was collected by venipuncture and nine volumes immediately, were mixed with one volume of 0.1M sodium oxalate. The plasma was treated with tricalcium phosphate* as follows. 1 cc. of a 0.008M suspension of tricalcium phosphate was transferred to a small test tube and centrifuged. The supernatant water was poured off and the tube drained. One cubic centimeter of plasma was then mixed with the packed tricalcium phosphate. After ten minutes of incubation at room temperature the adsorbent was separated by centrifugation. The plasma obtained no longer clotted when mixed with thromboplastin and calcium chloride. By this procedure components A and B are removed, but the concentration of the labile factor is only minimally affected, as determined by preliminary studies.

On adding this treated plasma to stored human plasma, the prothrombin time is strikingly shortened. By determining the amount of plasma that has to

TABLE I THE EFFECT ON THE PROTHROMBIN TIME RESULTING FROM THE ADDITION OF VARYING AMOUNTS OF THE LABILE FACTOR (PRESENT IN FRESH AND STORED PLASMA) TO STORED HUMAN PLASMA

*The plasma was treated with $\text{Ca}_3(\text{PO}_4)_2$ to remove components A and B.

†The prothrombin times of the stored plasma were: rabbit plasma 10 sec., dog plasma 22 sec. and human plasma 26 seconds.

*To prepare tricalcium phosphate suspension. 158 Gm. of trisodium phosphate are dissolved in 1000 cc. of distilled water. Separately 66.6 Gm. of anhydrous calcium chloride are dissolved in 1000 cc. of distilled water. The calcium chloride solution is poured into the trisodium phosphate with thorough stirring. The pH is adjusted to 7. The precipitated tricalcium phosphate is washed repeatedly by decantation until the sodium chloride is removed. The volume is brought to 1 L. thus making a 0.2M suspension. From this stock a 0.008M solution is prepared by mixing 4 cc. with 96 cc. of distilled water.

be added to a fixed amount of stored plasma in order to reduce the prothrombin time to an arbitrarily selected value, the relative concentration of the labile factor can be calculated. The value taken as standard was 20 seconds, the prothrombin time which is obtained when fresh oxalated human plasma treated with tricalcium phosphite is added to stored oxalated human plasma in the proportion of 1 to 10. It can be seen from Table I that only one part of rabbit plasma needs to be mixed with 500 parts of stored plasma to reduce the prothrombin time to 20 seconds while dog plasma will bring about the same reduction in a dilution of 1 to 100. These findings indicate that fresh rabbit blood contains fifty times and dog blood ten times as much labile factor as human blood.

Fig 1—The influence of varying concentrations of the labile factor on the prothrombin time of fresh normal human plasma

When rabbit blood was stored for seventeen days the labile factor decreased to such an extent that a dilution of 1 to 50 was required to obtain a prothrombin time of 19 seconds. Apparently the labile factor decreased approximately to one tenth of its original concentration in seventeen days of storage. A similar decrease occurred in stored dog plasma. Due to the initial high concentration in rabbit and dog plasma the effect of the loss of labile factor in storage as indicated by an increase in prothrombin time is not so striking as in human plasma.

It will be observed that as the volume of fresh plasma treated with tricalcium phosphite added to stored plasma is increased the prothrombin time decreases to a minimal value that remains constant over a rather wide range (Table I). Munro and Munro reported similar findings. The higher the concentration of the labile factor, the lower the minimal constant value. Thus

rabbit plasma reduces the prothrombin time of stored oxalated human plasma to 7 seconds, whereas human plasma lowers it only to 12 seconds

The Effect of Different Concentrations of the Labile Factor on the Prothrombin Time of Fresh Human Plasma—In 1945 one of us (A J Q) observed that the prothrombin time of fresh human plasma diluted with progressively increasing amounts of rabbit plasma treated with aluminum hydroxide did not give a typical hyperbolic curve such as is obtained by dilution with saline, but one in which a minimal value was quickly attained and which remained unchanged over a wide range of dilutions.⁶ Prothrombin curves obtained by using saline or fresh human or rabbit plasma treated with tricalcium phosphate as the diluent of fresh oxalated human plasma are shown in Fig 1. It seems definite that the high concentration of the labile factor was responsible for the shape of the curve obtained with rabbit plasma, because when fresh human plasma treated with tricalcium phosphate was employed as diluent, thereby keeping the concentration of the labile factor low and constant, the curve approximated that obtained with saline. It is not possible to explain the action of the labile factor on the shape of the curves, but it is obvious that the factor is a key substance in the formation of thrombin.

DISCUSSION

One of the most striking observations recorded in this study is the low concentration of the labile factor in human blood. It is certain that this accounts in part for the relatively long prothrombin time of human plasma as compared with that of many of the common laboratory animals such as the rabbit and the dog. But there must be other factors, as shown by the result of the simple experiment of mixing oxalated human plasma with an equal volume of fresh rabbit plasma treated with tricalcium phosphate to remove component A and B but not the labile factor nor fibrinogen. In this mixture the concentration of the labile factor was increased about twenty-five fold, yet the prothrombin time was decreased only from 12 to 10 seconds. If rabbit plasma is diluted with an equal volume of fresh human tricalcium phosphate treated plasma, which produces a mixture having about the same concentration of labile factor, a prothrombin time of 7 seconds is obtained. Since the prothrombin times are not a linear function of prothrombin activity but vary according to the well known hyperbolic curve, and since these values of prothrombin time are in the steep part of the curve, the difference between 10 and 7 seconds is much greater than would be shown by the simple arithmetic ratio.

Studies on the concentration of the labile factor in healthy subjects show that it is remarkably constant. No means so far has been found to alter specifically and exclusively its concentration. It still remains to be determined whether its level is altered in certain pathologic conditions. In the well recognized types of hypoprothrombinemia such as vitamin K deficiency, dicumarol poisoning, and hereditary deficiency of either component A or B, no significant change in the concentration of the labile factor occurs. In recent years cases of hyperprothrombinemia have been reported. Many of these are based on prothrombin time determinations of highly diluted plasma, often with complete

disregard of the fibrinogen concentration, which as Deutsch and Gerarde have shown, can definitely influence the prothrombin time of highly diluted plasma. Most of these cases can probably be dismissed as insignificant but authenticated cases deserve reinvestigation to determine what factor of the prothrombin complex is responsible.

The disappearance of the labile factor in plasma when stored is more easily detected in human than in dog or rabbit plasma because its concentration is relatively low. Oxidation appears to be responsible for the inactivation of the labile factor since plasma covered with a layer of mineral oil does not show nearly as rapid a decrease of this agent. Its instability appears to be associated with decalcification. Thus native hemophilic plasma shows a much slower decrease of the labile factor than oxalated or decalcified hemophilic plasma.⁸ Mechanism of action and relationship of this new factor with the other clotting agents require further investigation. The complexity of the problem is plainly shown by the results in Table I.

In addition to the decrease of the labile factor it is obvious that another change occurs in stored plasma. Thus whereas mixing fresh human plasma with an equal volume of rabbit plasma treated with tricalcium phosphate reduces the prothrombin time only to 10 seconds the same mixture with stored instead of fresh human plasma will have a prothrombin time of 7 seconds. Something obviously happens in stored plasma which increases the activity of the labile factor. Whether this is due to the liberation of a specific substance on which the activity of the labile factor depends remains to be determined. It is interesting to speculate if this has any relation to the Ae globulin of Seegers and associates⁹ especially since they have obtained evidence that one form the plasma Ae globulin, is converted to a more active modification which they named serum Ae globulin.¹⁰ It should be stated that the labile factor is not Ae globulin, since agents such as tricalcium phosphate adsorb the latter but not the labile factor. It is difficult to correlate the present observations with the investigations on Ae globulin, since in those studies the influence of the labile factor is ignored and therefore not controlled. Its absence in the reaction mixture is not ruled out however since lung thromboplastin which was employed may contain an appreciable quantity as a contaminant.¹¹

According to the most recent reports of Ware and Seegers¹² they still hold the view that their purified prothrombin is converted to thrombin solely by thromboplastin and calcium and that their Ae globulin acts merely as an accelerator. This view is not in harmony with the earlier findings of Mertz, Seegers and Smith¹³ and of Quick¹⁴ that the conversion of prothrombin to thrombin is a stoichiometric reaction. It seems fairly certain that in this reaction the labile factor is indispensable. Owen¹⁵ voices a similar opinion. "In 1944 and 1945 I was able to show that without factor V no thrombin is formed."

With the discovery of clotting factors other than the classic four of the Morawitz and Fuld and Spino theory, it becomes exceedingly important to inquire how the accuracy and reliability of the prothrombin time determination are

affected. Perhaps it is best at this time, when the whole problem of coagulation seems to be entering into a new phase of development, for the sake of simplicity to view the process as involving two major groups of factors: first, the factors that constitute the prothrombin complex, second, thromboplastin and substances related to its activation. If the prothrombin time as determined by the one-stage method is normal, one can immediately conclude that the factors constituting the prothrombin complex are normal and that the defect is in the thromboplastin or in its activation. Known conditions of the latter class are hemophilia, acquired hemophilia-like disease,¹⁷ and hemophilia-like disease of swine.¹⁸ Hypoprothrombinemia becomes then a generic term including congenital deficiencies of components A and B and the labile factor as well as the various types of acquired conditions in which the prothrombin time is prolonged.

Neither the one-stage nor the two-stage method can be any longer considered specific for the determination of any one constituent of the prothrombin complex. It is clear that the prothrombin time of the one-stage method is a resultant of three distinct constituents, A, B, and the labile factor, and there may actually be other agents not yet recognized. The prothrombin time is therefore essentially a measure of prothrombin activity. The one-stage test has the advantage that it is performed on plasma in which physicochemical and chemical changes have been kept at a minimum. Since it has been demonstrated that the prothrombin time of native (undecalcified) and oxalated plasma is essentially the same,⁹ the only major alteration of the blood in the one-stage method, namely the removal of calcium by oxalate, does not cause any fundamental disturbance. The thromboplastin employed, a saline extract of rabbit brain dehydrated with acetone, while essentially a crude preparation, has the advantage that it is almost entirely free of the labile factor and other constituents of the prothrombin complex. This is because rabbit brain can be obtained almost completely bloodless.

The determination of prothrombin activity in terms of prothrombin time of the one-stage method is valuable because evidence is accumulating both experimentally and clinically showing that it correlates with hemostatic effectiveness. Thus a prothrombin time of about 20 seconds has been found to mark the beginning of the bleeding tendency whether the deficiency is due to decrease of component B from dicumarol poisoning¹⁹ or from congenital lack of component A.²⁰ It is becoming apparent that the one-stage method is a delicate and sensitive test that requires meticulous attention to details. The only satisfactory thromboplastin is rabbit brain dehydrated and prepared exactly as originally outlined by one of us (A. J. Q.). Since changes occur in plasma during storage which affect the prothrombin time, the determination should be done on plasma within one or two hours after collection.

The two-stage method of Warner, Brinkhous, and Smith likewise will require reinvestigation to determine the impact of the new prothrombin factors. The use of dehydrated lung extract as thromboplastin needs critical examination since this product is likely to contain the labile factor as a contaminant.

Likewise there is danger that even the fibrinogen employed may contain the labile factor as an impurity. This probably explains why the two stage method failed to disclose loss of prothrombin activity in stored plasma and led Loomis and Seegers²¹ into the errors of attributing the delayed prothrombin time of stored plasma to an alteration of fibrinogen and completely overlooking the true cause, namely the loss of the labile factor.

SUMMARY

The labile factor of the prothrombin complex is not adsorbed by tricalcium phosphate and similar adsorbents. It disappears from stored oxalated plasma due to destruction by oxidation and this accounts for the decrease of prothrombin activity in stored plasma.

A simple method for assaying the labile factor in plasma was developed. The plasma to be assayed is treated with tricalcium phosphate and then the amount is determined which must be added to a fixed quantity of stored human plasma to reduce the prothrombin time to an arbitrarily selected value. By this procedure it was found that rabbit plasma contains fifty times and dog plasma ten times as much labile factor as human plasma.

The prothrombin time is reduced to a markedly shorter value when the labile factor is added to stored plasma than when added to fresh plasma, thus suggesting that something is elaborated in stored plasma which increases the activity of the labile factor.

The influence of the labile factor on the accuracy of the prothrombin activity determinations and its variations in physiologic and pathologic conditions are discussed.

BLOOD AND BONE MARROW CONCENTRATION OF ATABRINE AND ITS ROLE IN APLASTIC ANEMIA

CAPTAIN LEO G. PARMER*

MEDICAL CORPS ARMY OF THE UNITED STATES

THE value of Atabrine in the suppression and treatment of malaria during the recent war cannot be overestimated. Despite the large number of troops to whom the drug was regularly administered very few signs of toxicity appeared. Most prominent were the cases of Atabrine dermatitis complex. The most severe reactions caused by Atabrine therapy were in the cases of aplastic anemia reported by Custer.¹ He described fifty-seven fatal cases in troops from the Asiatic Pacific Theater. This was the first comprehensive study indicating that Atabrine affected the hematopoietic system. Previously Shannon and co-workers² showed that the Atabrine concentration in leucocytes was much higher than in plasma or erythrocytes. It might be inferred from this observation that since Atabrine is concentrated in the leucocytes it might act as a toxic agent on these cells and perhaps aid in the pathogenesis of aplastic anemia.

Aplastic anemia primarily involves the bone marrow and it therefore was of interest to determine the concentration and the rapidity of elimination of Atabrine from the hematopoietic organs. In aplastic anemia the myeloid leucocytes are much more severely affected than are the lymphocytic leucocytes and information was needed as to whether Atabrine entered both these cells in comparable concentrations.

This report presents the results of a systematic study of the Atabrine concentration in bone marrow and in various blood elements of the rabbit and chicken and the rate of excretion. These results are correlated with some observations in man.

EXPERIMENTAL

Rabbit Experiments—The concentration of Atabrine in the bone marrow and blood of rabbits was determined at various intervals after a single injection of the drug. Rib marrow levels were taken as representative of those in flat bones, and femoral marrow was analyzed for levels in long bones. Liver, spleen, thymus and mesenteric lymph nodes were analyzed for comparison of visceral levels with marrow levels.

Method Each of twenty-one albino rabbits weighing about 2.5 kilograms was injected with a single intramuscular dose of 8 mg per kilogram of Atabrine dihydrochloride. The animals were then sacrificed at intervals of from four hours to twenty-six days. Three animals were studied in each group and the results were averaged. The blood was collected in potassium oxalate and centri-

Present address: Medical Division, Food and Drug Administration, Washington, D. C.

fused to separate the plasma and red cells from the buffy coat containing the white cells. All specimens of tissue and blood were analyzed in duplicate using Masen's photofluorimetric method.³

Results Table I shows the concentration of Atabrine in the tissues studied. After four hours the spleen contained 40.6 mg per kilogram as compared with 7.7 mg per kilogram in the liver. The bone marrow Atabrine varied between 3.1 and 5 mg per kilogram, indicating that there was only a slight difference, if any, between the Atabrine level in flat bone marrow and in long bone marrow. The concentration of the drug in leucocytes was much greater than that found in either plasma or erythrocytes.

TABLE I ATABRINE CONCENTRATION (MG/KG) IN TISSUES OF RABBITS AFTER AN INTRA MUSCULAR INJECTION OF 8 MG/KG OF ATABRINE DIHYDROCHLORIDE

	TIME AFTER INJECTION						
	4 HOURS	4 DAYS	7 DAYS	11 DAYS	13 DAYS	18 DAYS	26 DAYS
Rib marrow	5.08	0.59	0.37	Trace	0	0	0
Proximal femoral marrow	4.38	1.02	0.33	Trace	0	0	0
Distal femoral marrow	3.11	0.69	0.21	Trace	0	0	0
Plasma	0.08	Trace	0	0	0	0	0
Erythrocytes	0.27	Trace	0	0	0	0	0
Leucocytes	1.87	Trace	0	0	0	0	0
Lymph node	1.70	1.35	1.05	0.41	0.19	0.29	0.19
Thymus	2.70	0.57	0.10	0	0	0	0
Liver	7.78	1.25	0.46	0.05	0.11	0	0
Spleen	40.62	1.96	0.44	0.11	0.14	0	0

Four days after the administration of Atabrine the spleen still had the greatest concentration of drug, but this level had dropped more precipitately than had any of the others. Despite a significant level in the bone marrow, the peripheral erythrocytes, leucocytes, and plasma were practically free of Atabrine. During the second week after injection the levels in all tissues decreased rapidly. The thymus contained no Atabrine on the eleventh day, where as the lymph nodes contained the drug as late as twenty six days after injection.

Chicken Experiments—Chickens are frequently utilized in studying the effects of antimalarial drugs, and therefore experiments were conducted to determine the concentration of Atabrine in the marrow and blood elements of this animal. Liver and spleen again were analyzed for comparison. Since chicken erythrocytes are nucleated, the comparative concentration of Atabrine in the leucocytes and erythrocytes was of interest.

Method Eight Leghorn hens weighing about 1.7 kilograms each were injected with single intramuscular doses of 8 mg per kilogram of Atabrine dihydrochloride. They were sacrificed at intervals of four hours and four, seven and ten days. Two birds were examined at each period. The tissues were treated as described in the rabbit experiments.

Results In general, at four hours the Atabrine concentrations in the chicken tissues were similar to those found in rabbits at a corresponding time after injection. The same relationship also existed between the various blood components, in that the erythrocyte concentration of Atabrine was higher than that of the plasma but much lower than that of the leucocytes (Table II).

TABLE II ATABRINE CONCENTRATION (Mg/Kg) IN TISSUES OF CHICKENS AFTER AN INTRA MUSCULAR INJECTION OF 8 Mg/Kg OF ATABRINE DIHYDROCHLORIDE

	TIME AFTER INJECTION			
	1 HOUR	4 DAYS	7 DAYS	10 DAYS
Proximal femoral marrow	5.08	0	0	0
Distal femoral marrow	6.11	0	0	0
Plasma	0.17	0	0	0
Erythrocytes	0.91	0	0	0
Leucocytes	3.32	0	0	0
Liver	21.64	0.21	0.07	0.04
Spleen	15.82	0.10	0.04	0.05

In the case of the chickens however the concentration of Atabrine in the marrow was reduced to zero within the first four days whereas this result was obtained only after thirteen days in the rabbits receiving a comparable dose of the drug. Another species difference was found in the spleen concentrations of Atabrine at four hours. In the rabbit the level in the spleen was much higher than that of the liver whereas in the chicken the reverse was found.

Observations on Human Beings—The purpose of these experiments was to compare the levels of Atabrine in the bone marrow with those found in the peripheral blood. By utilizing patients with either myelocytic or lymphocytic leucemia it was also determined whether Atabrine was found in similar concentrations in both lymphocytic and myelocytic leucocytes.

Method Two male subjects one normal and the other with a recurrence of symptoms from infection with vivax malaria, received Atabrine by mouth. Twenty four hours after completion of a course of 2.4 Gm. of Atabrine samples of peripheral blood and aspirated bone marrow were obtained. The bone marrow in these instances was markedly diluted with peripheral blood as compared with the bone marrow removed from rabbits after autopsy. Three additional subjects two with myelocytic leucemia and one with lymphocytic leucemia were given Atabrine orally for varying periods of time. The bone marrow and peripheral blood of three patients and the peripheral blood of the other two were studied.

TABLE III BLOOD AND BONE MARROW CONCENTRATION AFTER ORAL ADMINISTRATION OF ATABRINE DIHYDROCHLORIDE TO FIVE PATIENTS

PATIENT	CONDITION	LEUCOCYTES PER MM ³	ATABRINE LEVEL (μg × LITER)			
			PLASMA	ERYTHROCYTES	LEUCOCYTES	BONE MARROW
1	Malaria	7,000	42	-	-	836
2	Normal	5,500	77	55	-	1200
3	Chronic myelocytic leucemia	75,000	154	200	1285	2381
4	Chronic myelocytic leucemia	75,000	250	392	1589	-
5	Chronic lymphocytic leucemia	90,000	53	57	1864	-

Doses varied so that absolute levels between patients are not comparable

Results As in the rabbit experiments it was found that the bone marrow had a higher concentration of Atabrine than either the plasma or erythrocytes (Table III). The marrow concentration was as much as twenty times that of the plasma despite the fact that the marrow was mixed with peripheral blood.

The patients with leucemia, whose leucocytes were mainly myelocytic or lymphocytic cells, showed high concentrations of Atabrine in their white cells. It was thus determined that lymphocytes also had a high concentration of Atabrine similar to that found in myelocytic cells.

DISCUSSION

There have been but few reports dealing with Atabrine in the various blood elements and in bone marrow. Histologically, Martin and co-workers⁴ noted deposition of the drug in various tissues although the blood and bone marrow were not specifically mentioned. Siegel and Mushett⁵ reported that after large doses of Atabrine the bone marrow of rats showed an increase in the number of segmented and nonsegmented neutrophils. Reticulo endothelial cells containing vacuoles and basophilic inclusions occasionally were found. Significant levels in the bone marrow of chickens have been noted for at least two days after a single intravenous injection of Atabrine.⁶ Rather high levels were reported in rabbit marrow six days after a large oral dose.⁷ The present study confirms the species difference in that Atabrine remains in the bone marrow of rabbits longer than it does in the marrow of chickens. This species difference is mentioned because of the frequent use of chickens in the study of malaria and its treatment.

This investigation revealed that although Atabrine was found in the marrow of rabbits in high concentrations, the rate of disappearance of the drug from the marrow was not markedly different from that found in other tissues. Thus eleven days after a single dose of Atabrine the bone marrow as well as other tissues showed only very small amounts of the drug present. This level soon reached zero, indicating that marrow does not retain Atabrine for long periods of time. Two weeks after completion of the Atabrine course, in one of the leucemic patients the bone marrow was free of the drug. No studies for the detection of Atabrine degradation products were undertaken.

The British Army Malaria Research Unit⁸ showed that when Atabrine was given to patients with myelocytic leucemia the whole blood concentration rose as the white cell count rose. The present study, utilizing leucemic patients and analyzing the leucocytes directly, reveals that the lymphocytes as well as the myelocytic cells concentrate Atabrine in large amounts.

The question arose as to whether the ability of leucocytes to concentrate Atabrine and the inability of erythrocytes to do so was due to the fact that the leucocytes contain nuclei. It is recognized that there probably exists a fundamental difference between the nuclei of the red and white cells, nevertheless, in the chicken, in which the peripheral erythrocytes are nucleated, it was found that these cells did not have as high a concentration of Atabrine as did the white cells. From this it seems likely that in the chicken, and probably in other animals, none of the cells of the erythrocytic series take up large quantities of Atabrine and that therefore the high concentration of the drug in bone marrow is chiefly due to the presence of the drug in the myelocytic series of cells.

Although histologically the lymph node and thymus are quite similar and the concentration of Atabrine in both tissues was found to be almost the same at

TABLE IV LACK OF CORRELATION BETWEEN ATABRINE CONCENTRATION IN BLOOD CELLS AND IN TISSUES AND THE FATE OF THESE IN APLASTIC ANEMIA

	MYELOCYTIC LEUCOCYTES	LYMPHO-CYTIC LEUCOCYTES	ERYTHROCYTES	BONE MARROW	LYMPHATIC SYSTEM
Atabrine concentration	High	High	Low	High	High
Affected in aplastic anemia	Yes	No	Yes	Yes	No

four hours the subsequent finding was markedly different. Whereas no Atabrine was detected in the thymus at the end of eleven days the lymph nodes retained the drug for more than twenty six days.

An attempt has been made to correlate the present findings in animals and man. It is believed that the results obtained prove that the alleged relationship between Atabrine and aplastic anemia is not a direct one. It is not due to the fact that the drug enters the blood cells in high concentrations and by acting locally destroys them. Although Atabrine concentrates in both lymphocytic and myelocytic leucocytes, only the latter are affected in the disease. Although the drug does not enter the red cell series in large amounts these cells are severely affected (Table IV). There appears to be no correlation between concentration of the drug in various blood cells and those cells affected in aplastic anemia. Because of these findings and the further fact that of the millions of people who took Atabrine only a few developed aplastic anemia it may be presumed that the role of Atabrine in the pathogenesis of aplastic anemia falls into the idiosyncratic group of responses.

SUMMARY

After a single dose of Atabrine injected into rabbits the concentration in the bone marrow was much higher than that in the plasma or erythrocytes. More time was required for complete excretion of the drug from the bone marrow than from the peripheral blood.

Lymphocytic and myelocytic leucocytes both contained Atabrine in relatively high concentrations. Their ability to concentrate the drug is not due to the presence of a nucleus since the nucleated erythrocytes of the chicken do not develop as high a concentration of Atabrine as do the leucocytes.

Aspirated human sternal marrow, although greatly mixed with blood showed a concentration of Atabrine twenty times as great as did the plasma. The mesenteric lymph nodes of the rabbit retained considerable amounts of Atabrine long after the liver and spleen were free of the drug.

There appears to be no correlation between the height of concentration of Atabrine in the various blood cells involved in aplastic anemia and the damage evident in those same cells when aplastic anemia develops. The alleged role of Atabrine in the causation of this disease would appear to be in the nature of an idiosyncrasy.

THE EFFECT OF THE LIGATION OF THE PANCREATIC DUCTS AND OF PANCREATECTOMY AFTER DUCT LIGATION ON SERUM LIPASE

MARTIN M. NOTHMAN, M.D.,¹ DENNIS PRATT, M.D. AND JOSEPH BENNETT, M.S.
BOSTON, MASS.

THELRL is general agreement that ligation of the pancreatic ducts in dogs leads to an immediate increase of the amylase in the blood. This unity of opinion, however, does not exist regarding the effect of tying of the ducts on the blood lipase. Cherry and Crandall¹ have found an olive oil splitting enzyme in relatively large amounts in the blood of dogs after ligation of the pancreatic ducts. The results have been confirmed in two dogs by Dozzi² and in cats by Roe and Goldstein³ and Goldstein and co-workers.⁴ But Popper and Sotter⁵ did not observe an increase of blood lipase after the operation. Referring to the experiments of these investigators Braum⁶ believes that elevation of blood lipase after tying the pancreatic ducts has not yet been definitely proved.

Through the work of Comfort and Osterberg⁷ and Johnson and Bockus the experiments of Cherry and Crandall have become the basis for the clinical use of the serum lipase test in the diagnosis of pancreatic disease. However if Popper and Sotter's results are correct the serum lipase test is deprived of its essential experimental confirmation.

Since we have been interested in the evaluation of this test and its experimental foundations for years we were confronted with the following questions:

Does the serum lipase rise significantly after ligating the pancreatic ducts in dogs or not?

If the serum lipase does rise after ligation of the pancreatic ducts in dogs do these increased amounts of serum lipase originate in the pancreas?

Is the pancreas its only source?

What is the probable mechanism for the increase?

We began our investigations with the determination of the serum lipase before and after ligation of all pancreatic ducts on a large scale in order either to confirm Cherry and Crandall's results or to disprove them.

Our findings are based on observations on dogs chiefly female. Animals weighing from 6 to 11 kilograms were used. Those weighing about 20 pounds were preferable since removal of 15 to 20 cc of blood was necessary for the chemical determinations and on some dogs many of these had to be made. Blood was withdrawn from the heart by puncture or from the jugular vein.

Dogs were fed once or twice a day on a mixture of a prepared (commercial) dog meal evaporated milk and canned tomatoes with occasional supplements of ground meat when it was available.

¹From the Medical Clinic of the Boston Dispensary, Joseph H. Pratt Diagnostic Hospital and Tufts College Medical School.

Received for publication Aug. 1, 1947.

Anesthesia was induced with veterinary Nembutal* by the combined intravenous and intraperitoneal routes. The optimum method in our hands was to give initially an intravenous injection of about 0.2 cc per kilogram of body weight, after the peritoneal cavity was opened, the anesthetic solution was injected into it as needed.

Simple ligation and division of the pancreatic ducts, total pancreatectomy, partial pancreatectomy, and duct ligation followed by total pancreatectomy after an interval of several days, have been performed in the course of our studies. In the simple ligation and division of the ducts the pancreatic lobules were separated from both the duodenum and the pancreaticoduodenal blood vessels by sharp dissection of the delicate connective tissue adherent to the pancreas and by a gentle peeling action of the bare or gauze covered finger. The ducts were difficult to isolate, but with meticulous care few were missed. Almost always one large duct was fairly easy to identify and ligate. The other ducts usually one, sometimes two, and rarely three, were, with exceptions, proximal to the main duct. These ducts were invariably difficult to locate as they were always short and of fine caliber. In order to diminish chances of the pancreatic juice getting into the intestine and to facilitate healing, the omentum in 12 dogs was secured to the raw surface of the pancreas or interposed between the separated pancreas and duodenum. When ligation and division of the ducts had been done previously, total pancreatectomy proved to be more difficult, due to the intense inflammatory reaction in the region of the duodenum and pancreas, than total removal of the intact normal pancreas.

LIPASE METHOD

This method for lipase determination utilizes three blanks for every determination. B_1 represents the serum blank, B the olive oil blank, and B_2 the buffer blank.

B_1	B	B_2	TEST
2 cc H ₂ O	2 cc Oil emulsion	3 cc H ₂ O	2 cc Oil emulsion
5 cc Calcium acetate	5 cc Calcium acetate	5 cc Calcium acetate	5 cc Calcium acetate
5 cc Buffer	5 cc Buffer	5 cc Buffer	5 cc Buffer
1 cc Serum	1 cc H ₂ O		1 cc Serum

Incubate the four flasks at 37° for twenty-four hours. At the end of incubation add 10 cc of alcohol ether inactivating mixture to each flask. After having added a few drops of phenolphthalein, titrate with N/20 NaOH to a definite pink. Calculation: Add B_1 to B and subtract B_2 . Finally, subtract this result from the test.

Example	B_1 1.2 cc	B_1 1.2	Test 2.15
	B_2 0.85 cc	B_2 +0.85	-1.70
	B_3 0.35 cc	\hline 2.05	0.45 cc
	Test 2.15 cc	B_3 - .35	
		\hline 1.70	

Reagents —

Olive Oil Emulsion Gum acacia, 12.5 Gm., olive oil, 50 cc., H₂O, 100 cc. Pour the gum acacia and 50 cc of H₂O into a Waring blender and thoroughly mix. Then add the olive oil slowly and allow to mix to a pure white emulsion. Then add 50 cc more H₂O and mix to a uniform consistency. Store in the icebox.

Calcium Acetate $\text{Ca}(\text{C}_2\text{H}_3\text{O}_2)_2 \cdot \text{H}_2\text{O}$ Calcium acetate 20 Gm per liter of H_2O

Barbiturate Buffer Sodium diethylbarbiturate 5 Gm per liter of H_2O

Alcohol Ether Inactivating Mixture Alcohol 95 per cent 900 cc ether, 100 cc

The results of our experiments concerning the effect of pancreatic duct ligation on serum lipase are shown in Table I and Fig. 1

This enzyme was determined twenty eight times in twenty dogs before the operation. The average amount of serum lipase found in these twenty dogs was 0.6 unit; the lowest value was 0.2; the highest values were 1.3 and 1.6 in one dog, and 1.0, 1.1 and 1.2 in three other dogs; in all the other animals it was not higher than 0.8. All animals except Dog 20 showed a marked increase of the

serum lipase after the ligation of the pancreatic ducts. This rise begins within twenty-four hours after the operation. We determined the serum lipase in six dogs the first day following the ligation and we found values between 3.6 and 7.3. The average amount of serum lipase in these six dogs was 0.4; the average amount twenty-four hours after the ligation was 5.1; in other words on the average the values increased thirteen times over the initial values. On the second day after the operation the figures for serum lipase were still rising, the average being 7.0. After six or seven days the enzyme seemed to drop in some dogs; in others it appeared to rise; and in two dogs the highest values were found ten and twenty-two days after the ligation. Only Dog 20 showed an insignificant increase of serum lipase from 0.7 to 1.4 on the third day after the operation. It is possible, however, that from the fourth to the seventh day when determinations of serum lipase were not performed the values might have been higher.

These experiments prove definitely that after ligation of the pancreatic ducts there is almost invariably a rapid rise of the serum lipase and that this rise is of relatively long duration. However, the results do not justify the conclusion that the enzyme responsible for this rise originates in the pancreatic tissue. Other possibilities are to be considered. The pancreas may regulate

Fig 1

the lipase level in the blood by excretion of any excess of the enzyme which is produced in some different organ, and ligation of the ducts would lead to the elevation of the serum lipase merely by removing this regulating factor. If the serum lipase is of pancreatic origin, it should disappear after total pancreatectomy. If, however, serum lipase is derived from other sources than the pancreas and the pancreas is only the regulating factor, total removal of this gland will have the same effect as ligation of the ducts, an elevation of the serum lipase.

There were two valid methods whereby we could decide this question. We could determine the level of serum lipase after removal of the pancreas in nor

mal dogs or we could produce hyperlipisemia by ligating the ducts and then some days later removing the gland. Dozzi approaching the same problem chose the first method. Utilizing a modification of Cherry and Randall's technique he determined the serum lipase before and after pancreatectomy in a single dog. The values before the operation ranged from 0.1 to 1.15. On the first day after removal of the pancreas the serum lipase was 1.05 on the second day it was 1.7 and on the fifth shortly before the dog died it was 0.6. The experiments of Roe and Goldstein and of Goldstein, Jacobson, Telford and Roe performed on cats are not conclusive either and hence one cannot base a reliable opinion upon them.

TABLE II THE EFFECT OF PANCREATECTOMY ON SERUM LIPASE

DOG	SERUM LIPASE BEFORE PANCREATECTOMY		SERUM LIPASE AFTER PANCREATECTOMY (DAYS)				
			1	2	3	4	5
1	1.0		0.78	0.25	0.4		0.4
27	0.6	0.7	0.6	0.3	0.3	0.1	
28	0.5	0.8	0.6	0.4		0.	

Total pancreatectomy alone was done in three dogs (Table II) while in five dogs total pancreatectomy was carried out five to nine days following duct ligation (Table III and Fig. 2). As can be seen from Table II the dogs on which pancreatectomy was performed without previous duct ligation showed a steady decrease of serum lipase until death occurred five or six days after the operation. After tying all the pancreatic ducts in two dogs the corpus pancreatis was removed, leaving the processus hepaticus and processus uncinatus in situ. Thus from one half to two thirds of the total pancreatic tissue was extirpated. The pancreatic tissue that remained, although able to prevent diabetes was not sufficient.

<i>Death after pancreatectomy (day)</i>					
	5	41	34	6	5

to cause an elevation of the serum lipase. The effect of the removal of the pancreas on the level of serum lipase where the ducts have been ligated previously is clearly indicated in Table III (Fig 2). All five dogs showed a marked rise of the serum lipase after tying of the ducts. (These results are already included in Table I.) After removal of the pancreas there was an immediate drop of

Fig 2

the serum lipase. In three animals (Dogs 13, 14, and 18) the values for the lipase were almost zero on the second day following the operation. In the two remaining animals (Dogs 15 and 16) there was an essential decrease of the enzyme but it was less pronounced than in the other three animals.

Dogs 13, 16, and 18 died a few days after the second operation, but Dogs 14 and 15 were still living three and four weeks after pancreatectomy. We were surprised to find rising figures for serum lipase in these two dogs. One dog showed a value of 19 on the nineteenth day after the operation, and the other one showed 19 on the twentieth and 12 on the twenty-sixth day after the removal of the gland.

Our experiments demonstrate that serum lipase originates at least partly in the pancreas. This is proved by these three facts: (1) Tying of the pancreatic ducts leads to an immediate rise of the serum lipase. (2) Complete pancreatectomy leads to a steady decrease of the enzyme. (3) Total removal of the pancreas at a time when the level of serum lipase is still high, as a result of ligating the ducts, leads to a rapid diminution of the enzyme almost down to zero. We are not able to explain why other authors (Popper and Senter) did not succeed in producing elevated levels of serum lipase after ligation of the pancreatic ducts, but our findings that two to three weeks after total pancreatectomy serum lipase appears again to increase in amount even to values higher than before operation, show that this enzyme may also be derived from extra-pancreatic sources. The liver is a possible source. In studies concerning the enzymes of the bile in man, we have regularly found lipase in the contents of the gall bladder and the hepatic duct. (Unpublished data.)

The increase of serum lipase is apparently due to its absorption into the blood stream when the flow of pancreatic juice has been blocked. To substantiate this conclusion we have ligated the pancreatic ducts and drawn the tail of the pancreas through the abdominal wall, exposing the tip through the skin.

TABLE IV THE EFFECT OF LIGATION OF THE PANCREATIC DUCTS FOLLOWED BY THE PERFORMANCE OF A PANCREATIC FISTULA ON SERUM LIPASE

18	0.2			
32	0.4			

The serum lipase rose from 0.4 to 2.0 within forty eight hours. We then transected the tip of the exposed gland thereby permitting the pancreatic juice to escape. The first determination of the lipase two days after this operation showed that the lipase was already decreasing. When the fistula was well established, the serum lipase returned to normal, as is shown in Table IV. This demonstrates that the removal of the obstruction to the flow of pancreatic juice by means of a pancreatic fistula after duct ligation allows the escape of the pancreatic juice from the pancreas and therefore prevents the increase of the serum lipase level.

SUMMARY

Serum lipase is of both pancreatic and extrapancreatic origin. Its pancreatic origin is proved by the following facts: (1) Rise of serum lipase after ligation of the pancreatic ducts in all of twenty-one dogs. (2) Decrease of the serum lipase after total pancreatectomy. (3) Immediate drop of the serum lipase to almost zero in five days after total pancreatectomy, when the level for serum lipase previously has been raised by duct ligation.

The recurrence of serum lipase two to three weeks or longer after total pancreatectomy proves that there exists also an extrapancreatic source for the enzyme.

The mechanism which leads to the rise of serum lipase is absorption of the enzyme into the blood stream after blocking of the flow of the pancreatic juice. When ligation of the ducts is followed by the production of a pancreatic fistula, the elevated serum lipase drops to normal levels.

The authors wish to thank Miss Lillian Rosenberg, Miss Bernice Rubinowitch, and Miss Mary Powers for assistance in the technical determinations.

A RESIN ARTIFICIAL KIDNEY

E L MUIRHEAD M D AND ALLEN F REID PH D
DALLAS TEXAS

WASTE products excreted by the kidneys have been removed from the body via artificial routes such as peritoneal irrigations^{1, 2} and peritoneal irrigation and gastric lavage,³ and by in vivo dialysis⁴. The present report is concerned with preliminary observations on another technique by which such removal may be accomplished.

This artificial kidney consists of a resin bed composed of nine parts of Amberlite IR - 100 H* and one part of Deacidite †. The Amberlite is a typical cation exchange resin with exchange activity on $—O—COO^-$ and $—SO_3$ groups. The Deacidite is a typical anion exchange resin with exchange activity on $\equiv N(H_3O)^+$ groups.⁵

CONSTRUCTION OF RESIN BED

A coarse mesh of each resin is obtained by sifting through a 20 mesh screen. The finer particles require a positive push and care is needed to limit pulverization. Residual fine particles are removed by thorough washes. Deacidite tends to float and remixing is necessary before packing.

The resin mixture is placed in glass columns as in Fig 1. The column used had an inside diameter of 4 centimeters. Two lengths 50 and 85 cm. have been tested. Rubber stoppers accommodate the inflow and outflow tubes. The outflow tube is curved down and overlaid with glass beads. During packing the glass column is rotated while maintained at a 15 degree angle in order to minimize the formation of direct channels. Additional washes encourage packing and make particle escape through the outflow negligible. The stoppered ends are sealed with shellac. A second larger glass tube (outside diameter, 7.5 cm.) is likewise sealed in place about the primary tube and accommodates a temperature control water jacket.

Autoclaving is not feasible as it tends to break the resin particles mainly Deacidite. Sterility is attained with ethyl alcohol. The bed is thoroughly washed with distilled water. At this time the outflow water should give a negative or trace nitrogen test (no resin in solution).

OBSERVATIONS

One group of in vitro experiments included the following steps: (1) Conditioning of resin bed with Solution P†; (2) perfusion of resin bed with Solution P containing a high concentration of urea; (3) periodic measurement of the outflow urea concentration; (4) washing with Solution P and measurement of the amount of urea recovered. The volume flow was 100 cc per minute.

‡Solution P of Odel and Ferri⁶ has the following composition per liter: NaCl 6 Gm, KCl 0.1 Gm, CaCl₂ 0.1 Gm, MgCl₂ 0.1 Gm, NaH₂PO₄ 0.05 Gm, NaHCO₃ 3 Gm. The glucose was lowered to 0.5 Gm.

Fig 2 illustrates the results. In this experiment the 4 liters of Solution P contained 16 Gm of urea of which 4.78 Gm (30 per cent) were extracted. With this bed, urea concentration, and flow, the urea uptake amounted to 89 per cent at 2 liters. The wash curve mirrored the uptake curve and 4.9 Gm of urea were washed out.

Fig 1—A diagrammatic representation of the resin bed and connections as used in the in vivo perfusions. The description is in the text.

Fig 2—A demonstration of the urea uptake by the resin bed from Solution P containing 100 mg per cent of urea (16 Gm in 4 liters) and the subsequent urea discharge with solution P as wash. Each point represents the cumulative results up to that volume. The steady pH reading (glass electrode meter) is depicted. The following conditions pertained: resin dry weight 600 Gm, diameter of column 4 cm, length of column 80 cm, volume flow 100 cc per minute.

Heparinized blood perfused through the bed conditioned with heparinized Solution P yielded similar results (See Fig. 3)

Six dogs were subjected to *in vivo* perfusion with this apparatus on the fourth day following bilateral nephrectomy. For these experiments the resin column was tilted to a 45 degree angle. The lowest stratum was composed only of Amberlite since the Deacidite goes into solution more readily and was removed by this Amberlite layer. The intake tube was a Y tube one limb being

Fig. 3—Observation similar to the one in Fig. 1, heparinized blood used. Urea was added to the blood and the results were gauged as nonprotein nitrogen values. The initial nonprotein nitrogen concentration was 313 mg per cent. The same resin bed was used and the uptake and discharge of urea were approximately twice that in Fig. 1.

connected to the femoral artery and the other to a 20 liter reservoir of heparinized Solution P. One limb of the Y outflow tube was connected to a wash collection reservoir and the other limb was connected to an inverted siphon graduated acting as an air trap. The air trap led to a fine mesh cloth filter and on to the femoral vein. This filter removed fibrin strands and any resin particles escaping the bed. All connections were with rubber tubing. The distance from artery to intake tube was about 60 centimeters. An interposed manometer recorded the arterial pressure. The volume flow was maintained between 75 and 100 cc per minute.

The resin bed was filled with dog's blood or a substitute (plasma or albumin solution) in order to prevent hypotension. Perfusion was allowed for ten minutes then the blood residuum was collected in the air trap reservoir and the bed was washed with 1000 to 1500 cc of wash. The reservoir blood was reinfused into the vein while the bed was filling again.

Protocol, Dog 6 weight 15 kilograms. *In vivo* perfusion fourth day after bilateral nephrectomy. 50 mg heparin intravenously, wash solution. Solution P plus heparin 50 mg/per 1000 cc, size of bed 500 cc coarse resin bed conditioned with 2000 cc wash. temperature controlled 39° C. number perfusions

4, ten minutes each, flow, 70 cc per minute, total urea removed, 35 Gm (collected for 6 per cent blood contamination), no hemolysis, no reaction, blood pressure average 135 mm Hg, lived 25 more days, total 65 days

COMMENT

Preliminary experiments show promise for the resin artificial kidney. In vitro observations demonstrate an efficient means of adjusting pH, maintaining osmolar concentration, adjusting ionic disturbances, and removing waste products. In vivo perfusions have demonstrated a minimal reaction rate and an absence of hemolysis. Waste products are removed but a more efficient means of discharging the bed of residual blood prior to the wash is needed to increase the bulk removal of wastes and to prevent an excessive fluid intake into the recipient. Observations in this direction are being conducted at present.

Reactions to the resin (mainly Deacidite) were observed earlier with insufficient wash and failure to use the final Amberlite layer to remove soluble Deacidite. The reactions included restlessness, muscular jerks, and tachypnea.

Thorough preliminary conditioning of the bed with a heparinized solution is essential to avert clotting. Metal parts are not used since they encourage clotting of heparinized blood.*

The efficiency of this technique requires improvement. Translation of this technique to clinical use is not indicated at present.

The resin used for the removal of wastes (Amberlite) was primarily devised for the removal of cations, it does not seem to be as efficient in the removal of nitrogenous wastes and presumably other waste products. Resins more suitable to this purpose seem highly desirable.

CONCLUSION

A rather simple technique has been described for the removal of nitrogenous waste products. In vivo experiments have demonstrated minimal reactions, no hemolysis, and a simple means of maintaining pH and osmolar concentration steady. Removal of excessive amounts of cations may be attained by varying the conditioning of the resin.

THE RELATION OF PHENOL RETENTION TO UREMIA
AND
THE EFFECT OF PHTHALYL SULFATHIAZOLE AND STREPTOMYCIN
ON PHENOL PRODUCTION

STANLEY L WALLACE M.D., J MAXWELL LITTLE PH.D
AND J R R BOBB M.D
WINSTON SALEM, N C

FROM time to time various urinary constituents which are retained during renal insufficiency, have been implicated as primary factors in producing the symptom complex known as uremia. The depression of the central nervous system seen in uremia has been attributed to the accumulation of phenols^{1, 2}

The source of the phenolic compounds which accumulate during renal insufficiency has been shown by Marenzi to be the intestinal tract³. He demonstrated that, while in nephrectomized animals the blood concentration of total phenols increased rapidly in nephrectomized animals which had the entire intestinal tract simultaneously removed the blood concentration of total phenols either did not increase or increased only slightly.

It is generally thought that the phenolic compounds are produced in the intestinal tract by bacterial decomposition of ingested proteins. The specific bacteria which are responsible for the decomposition of proteins however, are not known.

The possibility has been investigated that as a result of decreasing the bacterial population of the intestinal tract by the oral use of phthalylsul fthiazole or streptomycin the production and therefore the retention of phenols might be diminished in nephrectomized animals. From the data obtained, the importance of the retention of phenolic compounds in uremia has been evaluated.

METHODS

The animals used were healthy, adult mongrel dogs weighing 6 to 14 kilograms and they were maintained before and during the experiment on a balanced diet (Ballard and Ballard). Daily control blood phenol determinations were done usually for two days on thirteen normal dogs. Four of these dogs then received orally a total of 0.5 Gm per kilo gram per day of phthalylsulfathiazole in divided doses for three days prior to bilateral nephrectomy and postoperatively until death. To another four animals a total of 0.5 Gm per day of streptomycin was given orally in capsules in divided doses for three days prior to the operative procedure and postoperatively until death. Five control dogs which received no medication were similarly nephrectomized. The operative procedure was a one stage bilateral nephrectomy under ether anesthesia with preanesthetic morphine and atropine. The adrenals were left intact.

Preoperative and postoperative phenol levels were done on each of the animals according to the method of Berahart and Schneider⁴. Fresh stool specimens from each animal were studied frequently by serial dilutions of 1 Gm wet weight of feces in Bacto Lactose

From the Department of Physiology and Pharmacology The Bowman Gray School of Medicine of Wake Forest College

broth before and during the period of drug administration to determine the coliform organism content. The greatest dilution of stool at which both acid and gas were produced in the broth was considered a measure of the number of coliform organisms in the fecal specimens. In the greater dilutions one is probably dealing with coliform organisms, but in the smaller dilutions any aerobic organisms producing gas from proteins or lactose may be included in the measurement.

All the animals were observed frequently until death, and the presence or absence of the various depressive and excitatory symptoms of uremia was recorded. The length of survival after operation was noted in all animals, and each animal was autopsied as soon after death as possible.

RESULTS

A preliminary study of the blood phenol concentrations in seventy-three determinations on twenty-four normal dogs yielded a mean value of 150 mg per 100 cc, with a range of from 0.82 to 230 milligrams. Only two of the

 ted 9 mg per cent total

The blood phenol concentrations of the control animals taken the day or the day prior to death were from 1.78 to 6.60 mg per 100 cc, with a mean of 4.16 milligrams. The animals receiving phthalylsulfathiazole had blood phenol concentrations at death of from 3.70 to 7.35 mg per 100 cc, with a mean of 5.54 milligrams. The animals given streptomycin died with blood phenol concentrations ranging from 1.54 to 2.23 mg per 100 cc, with a mean of 2.00 milligrams. Drug administration caused no significant change in the blood phenol concentrations in unoperated animals.

No animals showed evidence of predominantly increased nervous system irritability, although occasional coarse muscular twitchings were seen. All showed progressive nervous system depression terminating in death. Almost all of the animals showed severe anorexia, and they retched and vomited during the last forty-eight hours of life; one control animal had diarrhea. There was no significant difference in the uremic signs in the three groups. Some which received streptomycin showed earlier appearance of uremic signs than did the animals in the other two groups. The depth of depression was not always directly proportional to the concentration of blood phenols in the control and phthalylsulfathiazole groups.

Stool bacteriologic examinations revealed that within forty-eight hours of the start of oral phthalylsulfathiazole or streptomycin administration the coliform counts decreased from 10^6 to 10^7 organisms per gram of wet stool to 10^2 or less and this level was maintained until the death of the animal. In general streptomycin reduced the coliform counts somewhat more than did the sulfonamide.

Autopsy examinations revealed nothing of important significance.

DISCUSSION

Relationship Between Blood Phenol Concentration and Uremic Depression—Becker¹ and Harrison and Mason² demonstrated experimentally that signs of depression in uremia are accompanied by an elevation of the blood phenol concentration. This was confirmed clinically by Dickes¹ and Roen,³ among others, who reported that the correlation between elevated blood phenol concentration and the signs of narcosis was much closer than between the same signs and any other known chemical abnormality in uremia. They therefore concluded that there was an etiologic relationship between the two. This argument was strengthened by the fact that the clinical picture of phenol intoxication resembles the depressive aspects of uremia. On the other hand Nesbit, Burke, and Olsen⁴ in studying patients with uremia due to postrenal obstruction concluded that although the blood phenol concentration is elevated in uremia, uremic symptoms, including those of narcosis, are not always related to an elevated phenol concentration. They found no parallelism between the concentration of blood phenols and the intensity of symptoms and signs.

In our animals the administration of streptomycin effectively maintained the blood phenol concentrations at or near normal figures without altering the symptomatology. There appeared to be an earlier onset of symptoms and

earlier death in the streptomycin group. In addition although all control animals and those receiving phthalylsulfathiazole had increased blood phenol concentrations, there was no striking correlation between the severity of narcosis and the concentration of blood phenol. In several instances concentrations over 35 mg per 100 cc were attended by mild depression only while in others blood phenol concentrations lower than this were associated with severe stupor. These findings make it unlikely that blood phenols are etiologically related to the symptoms of depression in uremia. There must be some other retained urinary constituents which produce these symptoms.

The survival times in the control and phthalylsulfathiazole groups agree with those previously reported. Rodbard⁶ reported a survival after bilateral nephrectomy ranging from sixty to one hundred thirty hours with a mean of eighty five hours. Harrison and Mason reported a survival in dogs of from eighty five to one hundred twenty hours after the animals became completely anuric. The survival time of the group which received streptomycin was considerably less than that of the other two groups but because of the small number of animals in each group there is some doubt that this difference is significant. The explanation for this is not known since it is known that streptomycin is not absorbed from the intestinal tract in appreciable amounts. However it is possible that degradation or conversion products of streptomycin which would not be measured with the usual methods if they were not bacteriostatic, may accumulate and account for the earlier death.

Since the animals receiving streptomycin died earlier than those in the other two groups it might be argued that the lower phenol concentrations in the streptomycin group could be attributed to this fact. However the mean blood phenol concentration of the control group forty eight hours post operatively was 3.50 mg per 100 cc and the mean forty eight hour blood phenol concentration of the phthalylsulfathiazole group was 4.05 mg per 100 cubic centimeters. At a corresponding time the mean blood phenol concentration of the animals receiving streptomycin was 1.85 m_g per 100 cubic centimeters. Streptomycin therefore must effect the intestinal organisms responsible for the major portion of phenol production.

Phenol Production by Bacterial Action and the Effect of Chemotherapeutic Agents—Phthalylsulfathiazole⁸ and streptomycin^{9, 10} taken orally are poorly absorbed from the intestinal tract and thus they exert nearly all of their antibacterial effect within the lumen of the intestine.

Poth and Ross⁸ reported that phthalylsulfathiazole markedly depressed coliform and vegetative clostridial counts in human feces but it had no effect on spores or on the *Streptococcus faecalis*. On the other hand Miller¹¹ has shown in the rat that although coliform organisms are decreased by this drug there is no significant change in the number of aerobic or total anaerobic organisms or in the number of spores in the feces. Segel, Schweinburg and Fine¹² reported that this drug decreases gas formation in obstructed intestinal loops in rats by inhibiting the action of the coli aerogenes proteus group and certain of the clostridia. In our animals the coliform group was markedly

decreased in number by phthalylsulfathiazole administration, we did not study its effect on other organisms. However this drug produced no change in the course of the uremia nor did it diminish the usual increase in the blood phenol concentration. Apparently phthalylsulfathiazole does not act on those organisms in the intestine which are responsible for the production of phenols. Our results agree with those of Baueker and Schmidt¹² who reported that the administration of phthalylsulfathiazole to normal dogs resulted in no change in the concentration of phenols in the urine in spite of the almost complete inhibition of fecal coliform organisms. They concluded that the phenol producing organisms were not affected.

Oral streptomycin also markedly diminishes fecal coliform organisms.¹⁴ Zintell¹⁵ gave 1 Gm of streptomycin per day orally in divided doses to fifteen patients and noted a marked depression of fecal coliform and streptococcal organisms and a moderate diminution of clostridia. In comparison, succinylsulfathiazole, a drug similar in its action to phthalylsulfathiazole, diminished fecal coliform organisms moderately and clostridia and *St. faecalis* not at all. Smith and Robinson,¹⁶ using an oral dose of 30,000 to 300,000 units per kilogram in mice, found that streptomycin eliminated all gram-negative organisms and most gram-positive ones from the feces, leaving only a small number of gram-positive spore-forming organisms. We found a marked inhibition of coliform organisms by oral streptomycin, but we did not study its effect on other fecal organisms.

The specific identity of the organisms responsible for phenol production is not known. In considering the possibilities, it appears that the organisms probably would belong to that group manifesting great hydrolytic activity toward proteins, and that they also would be sulfonamide resistant and usually streptomycin susceptible. Of the organisms usually found in feces, the ones with the greatest hydrolytic activity toward proteins¹⁷ are *Clostridium sporogenes* and *Proteus vulgaris*. Of these two, the former is sulfonamide and streptomycin resistant while the latter is sulfonamide resistant but is usually sensitive to streptomycin. There is some basis then for the hypothesis that a small portion of phenol production may be attributed to *Cl. sporogenes* and that *P. vulgaris* is principally responsible for phenol production. It is also possible that the production of phenols requires the integration of the metabolic activities of more than one organism in the production of one or more precursors of phenols.

SUMMARY

Blood phenol determinations were done on three groups of dogs. After a control period, usually two days, phthalylsulfathiazole was administered orally to one group of four dogs in divided doses totalling 0.5 Gm per kilogram per day until death. In the same way streptomycin was administered orally to one group of four dogs in divided doses totalling 0.5 Gm per day until death. The third group of five animals served as a control. A one stage bilateral nephrectomy was done on the experimental groups three days after the drug administration was started and five days after the start of the experiment in

the control group. Fresh stool specimens from each animal were studied frequently by serial dilutions in Bacto Lactose broth to determine the coliform organism content.

The control mean blood phenol concentration was 1.50 mg per 100 cc, with a range of 0.82 to 2.30 milligrams. The control group died with a mean blood phenol concentration of 4.16 mg per 100 cc with a range of 1.78 to 6.60 milligrams. The phthalylsulfathiazole group died with a mean phenol concentration of 5.54 mg per 100 cc with a range of 3.70 to 7.35 milligrams. The streptomycin group died with a mean phenol concentration of 2.00 mg per 100 cc with a range of 1.54 to 2.23 milligrams.

None of the animals showed evidence of predominantly increased nervous system irritability, although occasional coarse muscular twitchings were seen. All animals showed progressive nervous system depression terminating in death. There was no striking correlation between the blood phenol concentrations and the depressive signs of uremia.

It is concluded that the retention of phenolic compounds is of little or no significance in producing the signs of nervous system depression seen in uremia.

Within forty-eight hours of the start of phthalylsulfathiazole and streptomycin administration the fecal coliform counts decreased from 10^6 to 10^2 or less and this level was maintained until the animals' deaths.

It is concluded that the predominant organism responsible for phenol production in the intestinal tract does not belong to the coliform group and that it is not inhibited by phthalylsulfathiazole but is inhibited by streptomycin. It is suggested that this organism is probably *P. vulgaris*.

The authors are indebted to Dr. Manson Meuls and Dr. MacDonald Fulton for advice on bacteriologic matters and to the staff of the Clinical Chemistry Laboratory for the blood sulfathiazole determinations.

MECHANISMS OF DESOXYCORTICOSTERONE ACTION

I RELATION OF FLUID INTAKE TO BLOOD PRESSURE

D M GREEN MD

SEATTLE WASH

ESSENTIAL hypertension is characterized by a type of sustained blood pressure elevation in which the usual mechanisms for counteracting rises in pressure do not appear to have been brought into operation¹ Preliminary results of investigations now in progress suggested that desoxycorticosterone may possess an ability, perhaps to a unique degree, to elevate mean pressure without production of secondary cardiac slowing or pulse pressure increase Consequently it seemed desirable to study the mechanisms by which this drug affects the height of the blood pressure level

The relatively rapid return to normal pressure levels following adequate desoxycorticosterone acetate (DCA) therapy in Addisonian crisis is usually considered to reflect the restoration of an adequate blood volume consequent upon correction of renal sodium and water loss On the other hand the hypertension which may develop subsequent to DCA overdosage both in patients with Addison's disease² and in normal subjects³ is not explicable on the basis of abnormal sodium retention⁴ or elevated plasma volume^{4, 5} and with few exceptions⁷ requires a period of weeks to months for its induction^{2, 4, 8} These considerations coupled with the absence of any conclusive demonstration of a contractile action on vascular musculature suggest that DCA induced hypertension may constitute a reaction to some more direct effect of the compound which precedes the pressure elevation in time

Knowledge of the more immediate action of DCA is concerned largely with its influence on water and electrolyte balance Although these effects are considered most frequently in relation to tubular reabsorption of sodium their clinical expression is perhaps more evident in terms of over all fluid exchange Cortical insufficiency is accompanied by a diminished capacity for water excretion⁹ while excessive DCA administration is followed by a diabetes insipidus like syndrome¹⁰ Since it appeared possible that the development of elevated blood pressure might be indirectly related to the profound influence of the salt retaining steroids on fluid exchange it was decided to study the temporal course of the two phenomena in a quantitative manner

EXPERIMENTAL PROCEDURES AND RESULTS

The experimental animals for the first group of studies consisted of twenty rats of the Sprague Dawley strain, weighing approximately 65 grams All animals were kept in separate cages and were fed on Purina laboratory chow Sodium chloride solution 0.86 per cent, was substituted for drinking water Consumption of food and fluid was unrestricted Fluid intake was measured daily and weight weekly The mean daily fluid intake per gram of body weight

From the Section on Experimental Medicine and Therapeutic School of Medicine, University of Washington

Received for publication April 10 1948

Fig 1—Alterations in fluid intake following DCA implantation in young rat

was calculated for each animal once a week by dividing the average daily intake by the mean weight for the week

At the end of the first week the animals were paired as closely as possible according to weight, unit fluid intake, and sex. Single 20 mg DCA pellets with an absorption time of four to six months were implanted beneath the skin of the back of each of the ten animals comprising the test group, using ether anesthesia. The animals of the control group were sham operated. Measurements of weight and intake were continued as described for a total of eight weeks.

The daily fluid intake of the control group per gram of body weight declined with age in linear fashion as illustrated in Fig 1. The test group, following implantation, manifested an abrupt and marked increase in intake, maximal within ten days, to a value twice that of the control group.

When this maximum increase had been attained, the unit fluid intake thereafter decreased with age in the test group also. However, the rate of de-

eline exceeded that displayed by the control animals so that with the passage of time the unit intake of the test group approached that of the control group despite the marked rise which had followed DCA implantation.

Studies of the relation of these changes to blood pressure and adenal function were carried out on a second test group of thirty rats. In addition to weight and intake determinations as previously described the blood pressure of each animal was measured weekly by an adaptation of the tail method¹¹. In order to secure the greatest degree of reproducibility it was found desirable to preheat the animals for twenty minutes at approximately 40° C and to make a series of ten readings at each determination the first five being discarded. Under these circumstances a group of eighteen control animals followed over a three month period manifested blood pressure levels which never exceeded 135 mm Hg.

Following a two week control period the test animals were divided into two groups. The twelve rats in the first group were each implanted subcutaneously with ten 20 mg DCA pellets. Six of the animals in this group were adrenalectomized the remainder were sham operated. The eighteen rats comprising the second group were implanted with single 20 mg DCA pellets. Adrenalectomies were performed on twelve animals and sham operations on the remaining six. The sexes were represented equally in each subgroup. Measurements of weight, fluid exchange, and blood pressure were continued as described for a total of twelve weeks.

Influence of Dosage—Following implantation all animals manifested the abrupt rise and secondary regression in intake previously described. However the maximum increase in intake was approximately three times as great at the higher dosage level. At the maximal point which was reached in approximately ten days the animals implanted with ten pellets were drinking more than their body weight of saline daily. They appeared to spend the greater part of the time lying on their backs the front paws clasped about the drinking tube from which they would drink rapidly and almost without interruption for minutes on end. During the period which comprised roughly the second week following implantation the animals appeared nervous and irritable and displayed muscular weakness and bouts of transitory paralysis during which the hind limbs were dragged. These phenomena resembled certain of the toxic manifestations which occur in man² and in the dog¹² consequent upon depression of serum potassium levels.

When the point of maximum intake had been passed and the period of regression toward lower levels of fluid exchange had set in the general condition of the animals spontaneously improved. They became tractable to handling once more and all evidences of muscular weakness disappeared.

At both dosage levels the blood pressure rose slowly and in reasonably linear fashion throughout the period of observation. However the slope of the pressure curve at the higher dosage was approximately twice as great as that at the lower level. The pressure of the animals implanted with ten pellets averaged 200 mm Hg at the end of twelve weeks as compared with a mean of 160 mm in those bearing a single pellet.

INTAKE 0.86% NaCl
GC/GM/DAY

BP
MM HG

Fig. 2—Relation of fluid intake and blood pressure following DCA implantation in young rats at two dosage levels

When the temporal relation of intake to blood pressure was studied, as illustrated in Fig. 2, it became evident that the earliest effect at both dosage levels was the change in fluid intake which had reached its crest and was declining before the blood pressure became elevated significantly above normal.

Fig. 3.—Comparison of the responses of adrenalectomized and sham-operated rats to DCA implantation at low dosage.

limits. It also appeared that the intensity of hypertension which subsequently developed was proportional to the maximal increase in fluid exchange while its rate of development was reciprocally related to the secondary regression in intake.

Influence of Adrenalectomy—The effect of adrenal removal on DCA action was studied because of observations that adrenalectomized dogs¹³ and patients with Addison's disease¹⁴ seemed more susceptible to overdosage than did normal

INTAKE 0.86% NaCl
CC/GM/DAY

Fig 4—Comparison of the responses of adrenalectomized and sham operated rats to DCA implantation at high dosage

subjects. This apparent hypersusceptibility has been attributed to a lack of antagonistic substances ordinarily secreted by the adrenal.¹⁴

The implantation of single 20 mg. pellets into adrenalectomized rats was followed by a smaller rise in fluid intake and a lower grade of hypertension than that produced in sham operated animals as illustrated in Fig. 3. These differences became less evident with an increase in dosage as shown in Fig. 4.

SUMMARY AND CONCLUSIONS

The immediate effect of DCA implantation in young rats maintained on isotonic saline solution was a rise in fluid intake. The more delayed responses to the drug included a secondary regression of intake values toward control levels and the reciprocal development of hypertension.

The degree of hypertension which developed appeared proportional to the dosage of the drug, the maximal rise in fluid intake and the subsequent rate of decline in intake.

No evidence was found that adrenalectomy sensitized the test animals to the actions of desoxycorticosterone.

The possibility is suggested that the hypertension induced by DCA over dosage may not represent a direct action but may be a compensatory mechanism for overcoming distortions in fluid and electrolyte balance produced by the drug.

We are indebted to Dr. E. Oppenheimer of Ciba Pharmaceutical Products, Inc., Summit, N. J., both for generosity in supplying desoxycorticosterone and for many helpful suggestions and criticisms throughout these studies.

ACTIVITY OF MICROBIAL ANIMAL PROTEIN FACTOR CONCENTRATES IN PERNICIOUS ANEMIA

E L R STOKSTAD, PH D, A PAGE, JR, BS, J PIERCE, MS, A L FRANKLIN,
PH D, AND T H JUKES, PH D, PEARL RIVER, N Y, AND R W HEINLE, MD,
M EPSTEIN, MD, AND A D WELCH, MD, CLEVELAND, OHIO

THE presence of an unidentified Factor X in concentrated antipermeious anemia liver extracts was shown in experiments with rats which received a purified diet containing hot-alcohol-extracted casein¹. Attention has been drawn² to the similarity of Factor X to the cow manure factor^{3, 4} which promotes growth in chicks and which in turn appears to be similar to the animal protein factor (APF) needed for hatchability of hens' eggs⁵ and for chick growth⁶.

In the present investigation it was found that a nonmotile, rod shaped organism from hen feces, when grown aerobically on simplified media containing no appreciable quantities of animal protein factor, could produce this factor,⁷ as indicated by assay with chicks on diets containing all the known B-complex factors together with high levels of soybean meal or of alcohol extracted casein. Concentrates were prepared from the growth medium, and by means of the chick assay their potency was standardized against refined liver extract, 10 USP units per milliliter, which produced a similar growth response in chicks. Concentrate I appeared to have between 50 and 100 per cent of the activity of the 10-unit liver extract when injected into chicks. It was prepared by preliminary clarification followed by precipitation with ammonium sulfate. It contained only approximately 0.5 μ g of toluic acid per milliliter, as indicated by *Streptococcus faecalis* R assay, and the value was not increased by treatment with a chicken pancreas "conjugase" preparation. Concentrate I was administered parenterally to a patient with pernicious anemia.

E. G., a 90 year old white woman, entered the hospital with an erythrocyte count of 1,290,000 per cmm, hemoglobin, 43 Gm per 100 ml, leucocyte count, 3,050 per cmm, hematocrit, 13 per cent, mean corpuscular volume, 100.5 c μ , mean corpuscular hemoglobin 33.3 μ g, mean corpuscular hemoglobin concentration, 33 per cent. The differential blood count, in per cent, was: neutrophils, 75, eosinophiles, 10, lymphocytes, 20.5, monocytes, 3.0. The neutrophils had highly segmented nuclei and were large cells. The erythrocytes showed marked variation in size and shape and appeared microcytic. The platelets were decreased in number.

Gastric analysis showed absence of free hydrochloric acid after stimulation with histamine. Stereal marrow aspiration revealed a marrow with increased cellularity, a relative and absolute increase in nucleated red cells, and a megakaryoblast content of 24.4 per cent.

From the Lederle Laboratories Division, American Cyanamid Company, Pearl River, N. Y., and the Departments of Medicine and Pharmacology, School of Medicine, Western Reserve University and University Hospitals, Cleveland, Ohio.

Received for publication June 3, 1948.

*The isolation of the active organism and the microbiologic production of animal protein factor concentrates were under the direction of Dr. Milton A. Petty, Lederle Laboratories Division, American Cyanamid Company. These studies will be the subject of a separate publication at a later date.

Lederle

Animal protein factor concentrate I was given in daily intramuscular dose of 10 ml (Table I) for nine doses. The patient was very ill with severe nausea and fecal vomiting. X-ray studies of the abdomen showed multiple distended loops of small intestine. A Miller Abbott tube was inserted, but after the third dose of animal protein factor concentrate the nausea and vomiting ceased and did not reappear. A single blood transfusion of citrated blood (500 ml) was administered when the erythrocyte count fell to 990,000 per cmm on the third hospital day. The patient made a rapid symptomatic recovery, becoming more alert and active and appetite returned. Thereafter the clinical course was uneventful.

A peak of 206 per cent reticulocytes occurred on the tenth day after the start of treatment with animal protein factor concentrate. This was followed by a prompt increase in the numbers of erythrocytes, leucocytes and platelets and in the hemoglobin level (Table I). The reticulocyte response was more delayed than the average response resulting from effective intramuscular therapy with liver extract, but the level reached by the reticulocytes was nearly that of the theoretic maximum.

A course of liver extract was started eighteen days after the beginning of therapy with animal protein factor concentrate. The patient received nine daily intramuscular doses

of 10 ml of purified liver extract (Lederle), each 10 ml containing 10 antipeptic anemia units. On the sixth day of treatment with liver extract there was a second, small reticulocyte peak of 6.0 per cent. The patient continued to improve.

Animal protein factor concentrate II was prepared by clarification with out precipitation with ammonium sulfate. It had between 25 and 40 per cent of the activity of 10-unit liver extract when fed to or injected into chicks. It contained about 0.02 μg of folic acid per milliliter, as indicated by assay with *St. faecalis* R, and the value was not increased by treatment with "conjugase." The concentrate also was assayed for total pteroylglutamic acid with chicks and was found to contain not more than 5 μg per milliliter. In another hospital this concentrate was administered parenterally to a patient with pernicious anemia, and the findings were placed at our disposal.

E N, an 80 year old white woman, entered the hospital with an erythrocyte count of 1,890,000 per cmm, hemoglobin, 7.7 Gm per 100 ml, leucocyte count, 2,400 per cmm,

Gastric analysis showed absence of free hydrochloric acid after stimulation with histamine. Sternal marrow aspiration revealed megaloblastic hyperplasia.

The presenting complaint was inability to walk. The patient had a cloudy sensorium. There was loss of vibratory sensation in the lower extremities.

Animal protein factor concentrate II was given in daily intramuscular doses of 10 ml (Table II) for twenty-four days. A reticulocyte peak of 9.7 per cent occurred on the seventh day after the beginning of treatment. There was a prompt increase in the number of erythrocytes and leucocytes and in the hemoglobin level (Table II).

Coincident with the hematologic response there was clinical improvement. The patient became better oriented and there was a return of appetite. The observers considered the clinical improvement to be moderately pronounced.

After thirty days of treatment the erythrocyte count had risen to 3,380,000 per cmm and hemoglobin to 10.8 Gm per 100 ml. The leucocyte count was 11,600 per cubic millimeter. There was a decrease in the mean corpuscular volume and in the mean corpuscular hemoglobin.

DISCUSSION

The results indicate that the concentrates of material produced microbiologically, and found to exert animal protein factor activity in chicks, also were active in inducing an hematopoietic response in pernicious anemia.

It is not possible to conclude that the hepatic and bacterial substances responsible for the activity in chicks are identical with the classic antipernicious anemia factor, since the so-called refined liver extracts used as well as the bacterial concentrates, are relatively crude materials. The nearly maximal reticulocyte response to concentrate I occurred on the tenth day while the patient given the weaker concentrate (II) had a submaximal reticulocyte response on the seventh day. With liver extracts of such potency (10 and 25 to 4 units per cubic centimeter respectively) a peak reticulocyte response would have been expected earlier than occurred in the first case. However, the apparent delay in the reticulocyte response may have been due to the very critical state and the advanced age (90 years) of the patient. On the other hand, the delay might reflect a difference in the rate of utilization of the active principles of liver extract and the animal protein factor concentrate.

Whether the second small reticulocyte response that followed the administration of the 10 unit liver extract to patient L. G. indicates that the liver extract was more effective than the animal protein factor concentrate is difficult to determine, since to permit subsidence of reticulocytosis the patient was without therapy for nine days after the course of animal protein factor concentrate was concluded. In any event the animal protein factor concentrate given parenterally produced an almost theoretically maximal reticulocyte response and an increase in the levels of erythrocytes, leucocytes, platelets and hemoglobin, in addition to causing satisfactory clinical improvement.

Conceivably, the bacterial extract contains forms or complexes of the antipernicious anemia factor that are utilized by the chick as sources of animal protein factor activity but are less effectively utilized by the human patient as sources of antipernicious anemia factor activity.

In the second patient the reticulocytes failed to attain a theoretically maximal level, but there, also, there was rapid improvement in the levels of erythrocytes, leucocytes, and hemoglobin, in addition to a satisfactory clinical response.

These findings show that a concentrate prepared from a bacterial filtrate contains a substance capable of producing an hematologic and clinical response in pernicious anemia. Whether the substance is identical with the anti pernicious anemia factor or the recently isolated vitamin B₁₂,⁹ shown to be active in pernicious anemia cannot be decided at this time.

SUMMARY

Concentrates of microbiologically produced material, highly active as a source of the animal protein factor, as measured by assay with chicks, were shown to be effective, when given parenterally, in producing an hematopoietic response in pernicious anemia.

EXPERIMENTAL AND CLINICAL STUDIES OF NEOHETRAMINE, A NEW ANTIHISTAMINIC AGENT

SIDNEY FRIEDLAENDER, M.D. AND ALEX S. FRIEDLAENDER, M.D.
DETROIT, MICH.

NEOHETRAMINE is one of a new group of synthetic antihistaminic agents found to produce symptomatic benefit in certain allergic states. It is the methoxy derivative of an earlier preparation, Hetramine¹ and is the pyrimidine isostere of another potent antihistaminic drug, Neoantergan.²

2-(N-dimethylaminoethyl N-p-methoxybenzyl)aminopyrimidine
monohydrochloride (Neohetramine)

The present report deals with the antihistaminic and antianaphylactic properties of Neohetramine as determined in the intact guinea pig as well as the clinical results observed in a large group of patients with various allergic syndromes.*

EXPERIMENTAL

Antihistaminic Effect in Guinea Pigs (Table I)—Antihistaminic activity was determined by treating guinea pigs with Neohetramine fifteen to twenty minutes prior to a toxic dose of histamine. 0.4 mg. per kilogram of histamine, calculated in terms of the base, was found to be uniformly fatal when injected into the penile veins of untreated guinea pigs. All animals which received 5 mg. per kilogram of Neohetramine intraperitoneally prior to this shocking dose of histamine lived, while 50 per cent of those treated with 1.0 mg. per kilogram of the drug survived this ordinarily lethal dose of histamine.

Antianaphylactic Effect in the Guinea Pig (Table II)—Guinea pigs 400 to 500 grams in weight, were sensitized by the subcutaneous injection of 0.1 cc.

From the Departments of Bacteriology and Medicine, Wayne University, College of Medicine.

Aided by a grant from Nepera Chemical Company, Inc., Yonkers, N. Y.

Received for publication April 20, 1948.

Neohetramine was supplied by the Department of Medical Research, Nepera Chemical Co., Inc., and is now distributed by Wyeth Incorporated, Philadelphia, Pa.

TABLE I PROTECTIVE ACTION OF NEOHETRAMINE IN HISTAMINE SHOCK

NUMBER OF GUINEA PIGS	NEOHETRAMINE (MG/KG I P)	HISTAMINE (MG/KG I V)	PER CENT SURVIVAL
15	None (control)	0.4	0
8	1.0	0.4	50
10	3.0	0.4	40
15	5.0	0.4	100

of horse serum and were given a challenging dose of 0.5 cc in a penicillin twelve days later. Protection against fatal anaphylactic shock was determined by giving Neohetramine intraperitoneally fifteen to twenty minutes prior to the shocking dose of antigen. All untreated controls died in typical anaphylactic shock. Seven out of ten animals which received 3.0 mg per kilogram of Neohetramine lived, while only four out of ten of those pretreated with 1.0 mg per kilogram of the drug survived. All guinea pigs receiving 0.1 mg per kilogram of Neohetramine died.

CLINICAL

Dosage and Toxicity—Clinical experience with Neohetramine indicated that symptomatic benefit, if it occurred, would become evident within thirty minutes after ingestion of the drug and last for several hours. Patients usually were instructed to take the drug at four- to six-hour intervals, but in some instances it was found necessary to use the drug more frequently in order to control symptoms. Those with periodic difficulty were advised to take the drug only when symptoms occurred. Initially 50 mg doses were prescribed and later were increased to 100 mg if clinical benefit was not evident. The optimum dose for most adults was found to be 100 mg, while 50 mg doses were employed with good results in children 6 to 12 years of age. Proportionately smaller amounts were used in younger children.

The incidence of side action from Neohetramine was less than that seen with other antihistaminic drugs previously studied.³ Several patients in this series who previously were found unable to tolerate antihistaminic medication were able to take clinically effective doses of Neohetramine without difficulty. Among 140 patients who were given Neohetramine, only seventeen (12 per cent) complained of side effects. Drowsiness, which is the most frequently encountered untoward reaction from antihistaminic drugs, was noted by five patients, five others reported gastrointestinal irritation, three complained of vertigo, and one patient each experienced weakness, tinnitus, diplopia, and pruritus. In no instance was the side action of a severe degree. Evidence of chronic toxicity as

determined by repeated blood counts and urine examinations was not encountered in those using the drug over longer periods of time. Periodic examinations in four patients who received an average dose of 200 mg daily for six months showed no abnormalities in urine or blood count.

Symptomatic Effect (Table III)—Neohetramine was used in 140 patients with one or more of the following allergic complaints: seasonal hay fever, non-seasonal allergic rhinitis, urticaria and angioneurotic edema, asthma, allergic

TABLE III. CLINICAL RESULTS WITH NEOHETRAMINE

CONDITION TREATED	NUMBER OF CASES	HELPED		NOT HELPED	
		NUMBER	PER CENT	NUMBER	PER CENT
Bronchial asthma	40	11	27.50	29	72.50
Vasomotor rhinitis	50	26	52.00	24	48.00
Hay fever	58	37	63.82	21	36.18
Urticaria					
Acute	6	6	100.0	0	0.0
Chronic	4	2	50.0	2	50.0
Dermatitis					
Atopic	3	0	0.0	3	100.0
Contact	2	1	50.0	1	50.0
Unclassified	4	3	75.0	1	25.0
Allergic headache	3	0	0.0	3	100.0
Allergic conjunctivitis	1	0	0.0	1	100.0

dermatitis, headache and conjunctivitis. Thirty of these subjects had two allergic syndromes such as rhinitis and asthma or hay fever and urticaria and since the effect of Neohetramine on each was not necessarily the same in that patient each symptom is listed separately in the accompanying table.

Seasonal Hay Fever. A beneficial effect on rhinorrhea, itching and sneezing was seen in 64 per cent of patients with acute hay fever due to pollen or fungus spores. In common with other antihistaminic drugs the relief following each dose was slight in some instances and marked in others but seldom complete. The many factors which influence symptoms in hay fever also affect the response to these drugs. Benefit is usually more evident early in the pollen season and on days when pollen or mold concentration is low. In general patients with mild symptoms, or those with some degree of immunity through desensitization therapy, obtain more relief than those with severe symptoms.

Allergic Rhinitis, Nonseasonal. Fifty-two per cent of this group obtained some symptomatic benefit from the drug. Rhinorrhea and sneezing were usually more favorably affected than nasal bloating.

Urticaria and Angioneurotic Edema. Relatively few of these cases are included in this series. In six patients with acute urticaria marked symptomatic action was apparent following the use of Neohetramine. Two patients with chronic urticaria were consistently relieved by the drug while two others failed to obtain any appreciable help.

Asthma. Approximately 27 per cent of asthmatic patients reported some help from the use of the drug. The degree of benefit in these patients in our opinion, was not striking.

Miscellaneous The drug was occasionally helpful in alleviating the pruritis associated with allergic dermatoses. Three patients with headache and one with conjunctivitis, all of allergic etiology, were not relieved by the drug.

COMMENT

Neohetramine compares favorably with other synthetic antihistaminic drugs previously studied. While antihistaminic and antianaphylactic activities as demonstrated in the intact guinea pig are somewhat less than those determined for several other drugs of this series, its symptomatic action in allergic states is approximately equivalent to other compounds when employed in the optimum dosage of 100 milligrams.³ A decided advantage which Neohetramine enjoys is the relative freedom from severe side effects accompanying its use. It appears to be especially indicated in those patients who are found to have a low tolerance for other antihistaminic drugs.

Experience with antihistaminic therapy has shown a rather wide individual variation in the clinical response to these compounds. A trial of several drugs in the same patient frequently will reveal one which is particularly effective and well tolerated. The incidence of symptomatic benefit from such medication is therefore increased by the availability of the newer members of this group of synthetic compounds. Our clinical experience would indicate that Neohetramine is a valuable addition to this growing list of antiallergic agents. It must, of course, be remembered that antihistaminic drugs are purely palliative medication and demonstrate no curative action in allergic disease.

SUMMARY

Neohetramine, [2-(N-dimethylaminoethyl-N-p-methoxybenzyl) aminopyrimidine monohydrochloride], prevented fatal shock from intravenous histamine in the intact guinea pig. A similar protective action was demonstrated in guinea pig anaphylaxis.

Oral administration of the drug afforded symptomatic relief to many patients with seasonal and nonseasonal allergic rhinitis, allergic dermatoses, asthma, urticaria and angioneurotic edema.

A relatively low incidence of side effects occurred with the use of Neohetramine. It was found particularly useful in patients unable to tolerate other antihistaminic drugs.

TRICHOSTRONGYLUS INFLUCTION IN HUMAN BEINGS NEED OF DIFFERENTIATION FROM HOOKWORM

LEONARD C EVANDER M.D. AND WILLIAM M. DOYLE
LOCKPORT N. Y.

IN 1916 Ransom,¹ in discussing the transmissibility of certain nematodes of ruminants to man stated that *Trichostrongylus* was not an exotic form occurring in remotely distant regions but a parasite which had a direct and immediate interest for American physicians. Though only a few cases of *Trichostrongylus* infection in human beings have been reported in the American literature we believe that this is due to a lack of knowledge regarding the differentiation of these ova from those of hookworm rather than to the rarity of the infection. In casual examinations of feces *Trichostrongylus* ova can be and probably often have been, mistakably identified as slightly atypical hookworm ova.

Loos² (1895) was the first to divide *Trichostrongylus* into four species. Jimbo³ (1914) undertook a statistical study of the spread of parasitic illness among the Japanese through feces examinations. He found that in Japan where ancylostomiasis is especially prevalent there were many people who had a peculiar type of *Ancylostoma* eggs which because of their great resemblance to *Ancylostoma* had been unjustly identified as such. The specimens appeared different from those described by Loos and therefore were named *Trichostrongylus orientalis*. Jimbo could not state what pathologic importance these worms had, but did recommend the use of oleum chenopodium as a therapeutic measure. Sandground⁴ (1936) who had infected himself with *Trichostrongylus* larvae to determine their longevity found that tetrachlorethylene and carbon tetrachloride were ineffective in expelling the worms. There was no diminution in the number of eggs after eight and one half years. In 1938 Schenken and Moss⁵ reported the first case of human infection with *T. colubriformis* in the Western hemisphere. They found a single adult worm in a surgically removed appendix. No definite information could be obtained regarding the source of the infection. Maplestone⁶ (1941) found a 9 to 25 per cent infection rate in India with a 10 per cent infection rate among 50 Europeans. He considered the recognition of *Trichostrongylus* important. Patients were often referred to as suffering from incurable hookworm infection because they were still passing eggs after several treatments with recognized efficient hookworm drugs. Because of failure to recognize the eggs the patients had received thymol carbon tetrachloride and oil of chenopodium which do have a certain degree of danger. Tsuchiya and Reller (1945) found *Trichostrongylus* ova in a patient who had worked as a farm laborer in the southern states. They thought it conceivable that the infection might have occurred through accidental ingestion of larvae.

From the Niagra Sanatorium

Received for publication March 4 1948

abdominal cramps and nausea. Therapy was discontinued on the sixth day. Prior to this treatment the patient had noted symptomatic improvement with the use of bland diet and Amphogel. At this time she refused to try any further drugs and was continued on the regimen until discharge on May 29, 1947. At the time of discharge there were occasional loose bowel movements, rare ova of *Trichostrongylus* in the feces, a sedimentation rate of 30 mm per hour, two eosinophiles in the differential count, and no evidence of anemia. The sputum had shown few to many colonies of acid fast bacilli during the flare up in September, 1946, but for six months prior to discharge all concentration and cultural examination of sputa and gastric lavages had been negative for acid fast bacilli. The pulmonary disease appeared arrested with pneumothorax.

When the ova had been properly identified, the patient's family were advised to have a checkup. Two brothers failed to show any ova on two occasions. The patient's mother, however, had many *Trichostrongylus* ova in December, 1946, and a few ova and an eosinophil count of seven in January, 1947. The mother reported that she had always been in good health. As far as she could remember she had never had any abnormal bowel movements. A specimen of the mother's feces was sent to the Army Medical School at Washington, D. C. The report stated that *Trichostrongylus* ova were present, again confirming the diagnosis.

COMMENTS

Detection of the ova of *Trichostrongylus* is difficult due to the small number usually present. A concentration and levitation technique may be required (Willis¹⁰). They are frequently mistaken by casual observers for the ova of hookworm, which they closely resemble. *Trichostrongylus* ova are characterized by a transparent shell membrane which is thicker and more lustrous than that of the hookworm. They are elongated, with the ends more pointed than those of the hookworm, though a great number will show some rounding at one end—like a hen's egg (Maplestone). The ova of hookworms average about 64 μ in length and 41 μ in width, while those of *Trichostrongylus* are much longer and slightly wider. Jimbo found the ova to average 83 to 90 μ in length and 41 μ in width, Tsuchiya and Reller 81 to 97 by 40 to 53 μ , with an average of 86 by 43 μ , O'Neal and Magath 76 to 86 by 44 to 47 microns. The ova of Patient J. L. in this report averaged 91 μ in length (range 80 to 100) and 44 μ in width (range 41 to 50), and those of her mother 88 μ in length (range 80 to 98) and 43 μ in width (range 40 to 46). The morula stage of *Trichostrongylus* will show at least sixteen divisions, a somewhat later stage of segmentation than that of hookworm ova. The individual divisions are equal in size, almost circular, and of a grapelike appearance. This is an important aid in differentiation. Two larvae were found, measuring approximately 285 μ in length and up to 24 μ in width. Jimbo has described the roundworm as being thin, delicate, sexually divided, of colorless to gray-white appearance, ranging from 380 to 670 μ in length and up to 83 μ at its widest portion.

According to Craig and Faust¹¹ several hundred worms are necessary to provoke marked clinical manifestations. Jimbo also notes that the severity of symptoms will depend on the number of parasites. Maplestone, however, states that as far as he knows the worms never give rise to any objectionable symptoms. Two of O'Neal and Magath's patients had intermittent blood tinged stools, while the third had abdominal cramps and frequent loose stools. The daughter (Patient J. L.) in our cases had diarrhea for several years while the mother had no symptoms. Yet the mother on occasions showed showers of ova.

Since so few cases of human *Trichostrongylus* infection have been reported the mode of infection is not definitely known. Chandler¹² believes that the infection occurs through the ingestion of contaminated vegetable matter rather than by penetration through the skin. It is possible that grazing lands are being seeded with eggs, since goats and sheep are natural hosts. Koino¹³ in experiments on mice traced the migration of the larvae and they seemed to follow the same route as hookworm larvae. He obtained penetration and migration to the lungs both by the oral route and through the skin. It would seem probable that human beings could acquire *Trichostrongylus* infection in the same manner as they do hookworm.

From all reports it appears impossible to eradicate the *Trichostrongylus* with the usual anthelmintics. As seen from previous investigations and from our own efforts the use of oil of chenopodium, thymol, carbon tetrachloride, tetrachlorethylene, as well as emetine hydrochloride, eubarbore and gentian violet is ineffective. Where *Trichostrongylus* has been mistaken for hookworm the patients have been subjected to needless objectionable and perhaps dangerous treatments.

CONCLUSIONS

There are we realize a number of questions left unanswered in this report. We do not know how the infection was acquired. We do not know whether the infection was acquired simultaneously by mother and daughter or whether it was transmitted from one to the other.

We cannot offer any course of therapy for the eradication of *Trichostrongylus*. The usual anthelmintics have been found ineffectual in the so called incurable hookworm infection which may be a *Trichostrongylus* infection.

In areas endemic for hookworm as well as in individual cases the ova of hookworm should be carefully examined and differentiated from those of *Trichostrongylus*. A lack of knowledge regarding the latter led to an original diagnosis of *Necator americanus* in our patient. If remembered in differential diagnosis, however, the shape, larger size and advanced segmentation of the *Trichostrongylus* ova cannot fail to attract the attention of the investigator.

The significance of the infection as related to the future health of patients can only be determined by prolonged follow up and by further case reports.

We wish to thank Dr. H. Tsuchiya, Washington University School of Medicine, St. Louis, Mo., and Lt. Col. G. W. Hunter and Major R. Traub of the Army Medical School, Washington, D. C. for checking the identity of the ova and Mr. M. Dietrich, the University of Buffalo Medical School, Buffalo, N. Y. for taking the photographs.

LABORATORY METHODS

ERYTHROCYTES IN URINARY SEDIMENT IDENTIFICATION AND NORMAL LIMITS

WITH A NOTE ON THE NATURE OF GRANULAR CASTS

RODNEY C LARCOM JR MD AND GEORGE H CARTER
BOSTON MASS

ALTHOUGH the importance of erythrocytes in the urine has long been recognized and their significance a subject of much discussion there has been little attempt to confirm their identification. The average laboratory technician fails to note the presence of red blood cells unless their number is definitely above the upper limits of normal.¹ Unfamiliarity with the varied forms of erythrocytes in urinary sediments, cursory examinations and inadequate technique are the main reasons for this failure. Addis noted that care was necessary to avoid passing over fragmented or partially lysed cells which may cast only faint shadows. The importance of the problem is emphasized by a 2 per cent incidence of hematuria in 20 000 consecutive patients in clinic practice² and a 10 per cent occurrence of erythrocytes in urinary sediments examined in our laboratory.

Two approaches have been used in this country to aid detection and to cope with the problem of identification. (1) the quantitative work of Addis and (2) tests for hemoglobin and related substances utilizing benzidine or orthotolidine. The first technique is tedious and inconvenient for clinical use while in the second the reagents may react with interfering substances and do not morphologically identify erythrocytes. Aware of the confusing variations in size shape and optical density of erythrocytes in the urinary sediment and of the responsibility of even an experienced technician for correct identification we have modified a tissue stain³ which appears to be specific for red blood cells.

Stock solutions

10 per cent aqueous solution of benzidine hydrochloride
(Merek)

20 per cent aqueous solution of sodium nitroprusside

300 per cent hydrogen peroxide (superoxol)

The benzidine and nitroprusside solutions keep from four to five months in brown bottles if not exposed to direct sunlight.

From the Medical Department, John Hancock Mutual Life Insurance Company
Received for publication Feb 9 1948

Working solutions

- A 0.1 per cent benzidine in 0.2 per cent nitroprusside
1 c c of the 1.0 per cent aqueous solution of benzidine
(stock) is diluted to 6 to 7 c c with distilled water
1 c c of the 2.0 per cent aqueous solution of sodium nitro
prusside (stock) is added and then distilled water to
10 c c

This solution is stable for about two weeks, it should be
discarded as soon as a precipitate is formed

- B 3.0 per cent hydrogen peroxide
1 c c of superoxol is made up to 10 c c with distilled water
This solution deteriorates in from three to four days

TECHNIQUE

A drop of sediment is placed on a slide and a drop of benzidine nitroprusside solution is added. Thorough mixing is accomplished by tilting the slide or by stirring with the cover glass. A drop of dilute peroxide solution is then added and carefully mixed.

Sediments of alkaline specimens, which do not stain readily, may be treated within the tip of the centrifuge tube with 1 or 2 drops of 10 per cent nitric acid to destroy the crystals and lower the pH. In our experience this has not caused hemolysis of red cells, probably because of the fixing property of urine and the presence of basic salts. After three washings with 0.9 per cent saline solution these sediments give results comparable to those attained in acid urines. Urine specimens of a high specific gravity, especially those containing preservatives, may react slowly to the stain, and should stand five to eight minutes before examination. Washing three times with 0.9 per cent saline solution should accelerate staining.

RESULTS

The erythrocytes are stained a deep blue-purple. This color may be pale, even a light blue if the cell has deteriorated. Some cells will have scattered deep blue punctate granules. Suspensions of yeast cells in normal urine less than twenty-four hours old may show a slight blue-green indescence which is not confused with the deeper color and less refractive appearance of the stained erythrocytes, while those over twenty-four hours old have no affinity for the stain. Leucocytes may take a pale-gray appearance in the cytoplasm with slightly dark and irregular staining of the nucleus. No granules have been observed in the cytoplasm of white blood cells or epithelial cells. Hyaline casts do not take the stain. The granules of fine and coarse granular casts have the deep bluish-purple hue of stained erythrocytes. The red blood cells of casts stain similarly to those free in solution. Fungi and spores show no response to the stain.* Pollen, diatoms, prostatic bodies, and other elements of urine have no affinity for the stain.

*We are indebted to Mr. Robert K. Steffa, Waterloo, Ia., for submitting fifteen species of fungi and three strains of yeast.

Fig 1.—A Red cells unstained B, Same cells stained. Note variable degree of stain intensity C, Suspension of yeast and red cells stained D Composite print. Granular casts (and few red cells) stained and unstained

STAINING REACTION

Since this stain seems to have a specificity for red blood cells the probable site of action is hemoglobin or one of its heme derivatives. Benzidine and oxidizing agents such as hydrogen peroxide react with acid solutions of hemoglobin to produce a blue color which according to Wu⁵ is exactly proportional to the amount of hemoglobin present. Bing and Baker⁶ consider this a pseudoperoxidase reaction. Benzidine and hydrogen peroxide react slowly with intact red cells in the urine to produce after some time a faint blue color. Sodium nitroprusside greatly increases the speed and intensifies the color of the reaction.

The mechanism of this reaction is very complex. It is known however that solutions of benzidine subjected to nascent oxygen or sodium ferrieyanide

rapidly form a deep blue precipitate. Solutions of benzidine and sodium nitroprusside form a similar precipitate only after standing for days. Benzidine, a fundamental dyestuff, is attached to the protein of red cells. Hemoglobin containing ferrous iron (Fe^{++}) is oxidized to methemoglobin containing ferric iron (Fe^{+++}) by hydrogen peroxide.⁷ The nitroprusside might react by forming a colored iron-cyanide compound or alter the reaction by its nitro group. Since we obtained no results under the conditions of our stain substituting sodium ferrocyanide, sodium ferriocyanide, or nitrites, it appears that nitroprusside may be a catalyst.

Because of these findings we feel that benzidine may be an indicator of an oxidation-reduction system⁸ which results in the oxidation of benzidine and the development of a deep blue color. The nitroprusside may act as a catalyst.

DISCUSSION

Identification—Most efforts at identifying blood in the urine have been directed toward the development of color tests for hemoglobin and related substances. Benzidine,⁹⁻¹⁰ toluidine,¹¹ and othotoluidine¹⁻¹² have been used as the reagents. These substances vary in their reactions with the pH of the urine,¹¹ ascorbic acid level,¹²⁻¹⁴ presence of iodides and bromides,¹² yeast or pus cells.¹⁰ Some investigators¹⁻¹¹⁻¹² have correlated the color reactions with quantitative erythrocyte counts of urinary sediments and claim that positive results occur only in the presence of a significant number of red blood cells. Others fail to find this correlation.¹⁵ Endtz¹⁶ has identified erythrocytes in the urinary sediment utilizing a benzidine stain. We found this technique to be slower acting and to give less intense color than the benzidine-nitroprusside method. The common practice of producing hemolysis of red blood cells by the addition of acetic acid to the sediment is unreliable, particularly in specimens containing preservatives.

To corroborate the varied appearance of red cells observed in submitted specimens, samples of normal blood were suspended in varying concentrations of sodium chloride with specific gravities of 1.004 to 1.040 with and without preservative tablets.* Studies of the sediments from these solutions substantiate our opinion of a great variation in size and appearance of red blood cells in urine specimens of different specific gravities and salt concentrations. The sediments from suspensions containing the preservative tablet had a more constant form of erythrocyte than those without the preservative tablet. Although the tablet liberates formaldehyde in solution, no inhibiting reaction upon the stain was observed. The buffer and slight acidifying effect of the preservative tablet creates a condition favorable to staining.

Of particular interest was the finding that the granules of fine and coarse granular casts stain the same dark bluish-purple of red cells and red cell debris which was found in the sediment of red cell suspensions. This would tend to

*Preservative tablet No. 4 Metropolitan Life Insurance Company specification contains: potassium acid phosphate, sodium benzoate, benzoic acid, Urotropin, sodium bicarbonate, mercuric oxide red.

indicate that the granules are particles of red blood cells which have been destroyed in the kidney and incorporated in the substance of the cast. This helps to explain the more serious implication of granular casts.

The efficacy of various preservative materials was evaluated by preparing suspensions of red cells in urine with preservative tablet, thymol, toluene, chloroform, boric acid, and formaldehyde. None of these materials inhibited the staining reaction, but only the formaldehyde and the preservative tablet satisfactorily preserved erythrocytes. From our suspension of erythrocytes in urine with one preservative tablet per ounce we obtained 100 per cent recovery of red blood cells even after seventy-two hours. This is greater than the 50 to 80 per cent recovery estimated by some investigators.¹ We have obtained identical counts per high power field and have had positive staining reactions on specimens that have stood at room temperature for as long as four to five months. There must be some breakdown of red cells in the kidney, however, as our findings on the nature of the granules of granular casts suggest.

Normal Limits—We were further interested in determining the number of red blood cells in the urinary sediment that may be considered within normal limits. Since the majority of urinalyses are on single voided specimens we endeavored to correlate the results of quantitative studies with those that might be expected on sediments from random specimens. It would appear that a normal individual may excrete as many as 600,000 red blood cells per twelve hour period.^{15, 16} This number of erythrocytes suspended in 300 cc of urine, the average twelve hour output of the quantitative studies, gave about 2 red blood cells per high power field by our standard technique. This technique consists of centrifugation of 15 cc of urine at 2,000 revolutions per minute for five minutes and examination of twenty high power fields of a drop of sediment placed beneath a $\frac{7}{8}$ inch cover slip. Although the findings of single voided specimens may vary,¹⁶ it would appear that the repeated presence of more than 2 red blood cells per high power field in the centrifuged sediment may indicate an increased loss of erythrocytes from one of the many sources of occult bleeding in the urinary tract. This estimate is supported by the laboratory findings in 3,000 consecutive single voided specimens from young men applying for employment. In this series 2,484 specimens were negative for erythrocytes. In sixty instances or only 2.0 per cent the specimens contained 2 to 3 red blood cells per high power field and only twenty-three samples or 7 per cent contained 4 to 5 red blood cells per high power field. These values support our findings on the correlation of quantitative studies that the repeated excretion of more than 2 red blood cells per high power field may be significant.

The count per high power field obtained by adding the staining solutions to the sediment directly upon a slide is lower than that of an untreated sediment. To avoid dilution the reagents may be added to the sediment within the tip of the centrifuge tube, carefully mixed, recentrifuged, and the supernatant fluid decanted. The sediment thus prepared will have approximately the original dispersion of red blood cells. In performing quantitative counts the staining solution may be used in diluting to the desired volume in the Addis centrifuge tube.

SUMMARY

A benzidine-nitroprusside stain for erythrocytes in the urinary sediment is described which we believe to be specific for red blood cells and fragments thereof. With this technique the red blood cells stain a deep blue purple and are easily distinguished from contaminants and other formed elements of urine.

The stain is based upon the pseudoperoxidase reaction of hemoglobin and benzidine. The nitroprusside may act as a catalyst.

The granules of fine and coarse granular casts take on the same bluish purple stain. This finding suggests fragments of red blood cells as the origin of the granules and helps explain the more serious implication of granular casts.

Erythrocytes may occur in the urinary sediment of normal individuals up to approximately 2 per high-power field. This level, determined by a conversion of the results of quantitative studies to the methods employed in analyzing single specimens, is supported by the results of our findings in 3,000 consecutive urinalyses in young men applying for employment. In this series, only 12 per cent of specimens contained more than 2 red blood cells per high power field.

The preservative tablet and formaldehyde are efficient agents for the preservation of erythrocytes. Thymol, toluene, chloroform, and boric acid are not satisfactory. None of these substances interfere with the stain for erythrocytes.

THE SPECTROPHOTOMETRIC DETERMINATION OF BLOOD pH

ROBERT C. RUTLEDGE, JR. M.D.

ST. LOUIS, MO

PROBABLY the most frequently used methods for the determination of blood pH are those of Hastings and Sendroy,¹ Hawkins,² and Shoek and Hastings.³ In recent years the electrometric determination of pH has been brought to a high degree of accuracy under certain well controlled conditions (especially by Nims⁴). However for purposes of clinical research the preceding visual colorimetric methods usually are considered adequate. There is one drawback which detracts from their usefulness—the observer must be experienced in the visual matching of colors. While this usually is not difficult with normal clear serum or plasma, slight amounts of hemolysis, hemoconcentration or bilirubinemia often confuse the inexperienced observer. In addition there are certain individuals who have great difficulty in distinguishing the difference between density and hue of color.

It was with these difficulties in mind that an objective spectrophotometric method of determining blood pH was sought for. Evelyn has described such a method but there is no technical provision for comparison with other methods. Therefore it was decided to apply spectrophotometric measurements to the method of Hastings and Sendroy¹ in such a manner that comparison with the visual method could be made on the same sample.

The principle of this method depends on the fact that the color of the indicator, phenol red, is different in acid and alkaline solutions. At a given pH the relative amounts of these two colors determine the final color of the solution. These two colors absorb light of widely different wave lengths and can be measured independently in the same solution with a suitable spectrophotometer. Since the relative amounts of these two colors are dependent upon pH, the measurement of these amounts constitutes an indirect measurement of pH.

Reagents—The reagents are those of Hastings and Sendroy. Detailed directions for their preparation are given elsewhere.*

Procedure—Four milliliters of the adjusted dye saline mixture are placed in a colorimeter tube and covered with a small amount of paraffin oil. Two tenths milliliter of serum or 0.4 ml. of blood are then added and the mixture is stirred gently with a glass rod. In the case of blood the tube is centrifuged to throw down the cells. The blank is prepared in a similar fashion substituting saline for dye saline. The optical density of the sample is determined at wave lengths 565 and 420 m μ after which the temperature of the solution is recorded.

*From the Department of Pediatrics, Washington University School of Medicine and the St. Louis Children's Hospital.

Received for publication Mar 10 1948

Letters and Van Slyke Quantitative Clinical Chemistry, vol 11, p 736-793

Calculation—The ratio of optical density at 565 $m\mu$ to optical density at 420 $m\mu$ has been determined for a number of solutions of known pH (Fig 2) For easy reference it is convenient to prepare such a graph from the data supplied by Evelyn⁴ After having calculated the ratio, read the pH from the graph This value is the uncorrected pH The true pH is obtained by applying the temperature correction⁶

$$\text{True pH} = \text{Uncorrected pH} - (0.42 - 0.01 T^{\circ} C)$$

Fig 1

Experimental—The absorption spectrum of phenol red in both acid and alkaline solution was determined with the Beckman spectrophotometer To a four milliliter portion of dye-saline solution were added 0.2 ml portions of strong acid or alkali The transmission of the resulting solutions was determined at various wave lengths (Fig 1) It is seen that measurements of the two colors are best taken at wave lengths 565 and 420 $m\mu$ to avoid undue interference

In order to check the data supplied by Evelyn for the relation of pH to the ratio of optical densities in dilute solutions of phenol red, a series of Sorensen's M/15 phosphate buffers was prepared,* the pH being accurately adjusted electrometrically To four milliliter portions of the adjusted dye-saline solution were added 0.2 ml portions of the buffer The optical densities of the resulting solutions were determined at wave lengths 565 and 420 $m\mu$ at 35°C

*By Mr J Earle Adler

The ratio of the densities was plotted against pH resulting in the curve shown in Fig. 2. As was expected when log ratio was plotted against pH a straight line resulted. These data are in good agreement with the data of Evelyn.

To compare the visual with the spectrophotometric method the pH standards described by Hastings and Sendroy were prepared. To insure stability these standards were prepared in sodium borate and boric acid instead of hydrochloric acid and sodium hydroxide. Test tubes of the same size were selected for use in the Coleman Junior spectrophotometer. The comparison was made as follows. To four milliliters of adjusted dye saline solution in a colorimeter tube were added 0.2 ml of serum. The usual blank was prepared and the tubes were warmed to 39° C., after which comparison was made with the visual standards.

Fig. —The relation between pH and the ratio of the optical densities at wave lengths 65 and 420 millimicrons

The tubes were then allowed to cool to room temperature and were placed in the spectrophotometer where the optical densities at 565 and 420 $m\mu$ were determined. The ratio of optical densities was calculated the corresponding pH read off the graph, and the temperature correction applied. The sera used were taken from both normal and pathologic subjects. The comparison of the two methods is seen in Table I along with other pertinent data. In some cases two or more observers participated in the visual comparison. These data indicate that the spectrophotometric method is at least as acceptable as the visual. In addition there is the added advantage that the personal error inherent in the

visual method is eliminated and this at the slight expense of the preparation of a graph and the selection of several colorimeter tubes. However, the errors of the colorimetric method *per se* are retained.

SUMMARY

An objective spectrophotometric method for the determination of blood pH is described. A comparison of the visual and spectrophotometric methods is presented showing an average difference of between .01 and .02 pH units.

Critical acknowledgement is made to Dr. Alexis F. Hartmann for advice and criticism during the course of this work and in the preparation of this paper.

A MICROMETHOD FOR THE DETERMINATION OF SERUM STREPTOMYCIN LEVELS*

ANDREW D HUNT, JR, M D, AND MARY B FELL, B S
PHILADELPHIA, PA

A MICROMETHOD for the assay of streptomycin in whole blood has been described by Foigacs and Kuceira¹ using agar plates seeded with a variant strain of *Bacillus subtilis*, Cohn *emend* Prasmowski, blood levels are estimated from the zones of inhibition produced by 0.1 ml aliquots of oxalated blood. Although it is a microtechnique for each determination, the construction of standard curves requires larger amounts of blood. Individual blood idiosyncrasies require that a separate standard curve be constructed for each patient. Furthermore, accuracy in the method requires maintenance of a uniform distribution of cells during the entire procedure, which is very difficult in bloods with low hematocrit values and elevated sedimentation rates. Since streptomycin does not enter the cells² and since the just mentioned difficulties seemed to stem from the presence of cells, it seemed desirable to modify the method for use with serum alone. Because of the decreased variables it was thought that one master standard curve might be generally applicable. The following technique was therefore developed.

Preparation of the Standard Curve—The serum from 12 ml of blood was required to determine the thirteen points on the curve. Final concentrations of 2, 3, 4, 5, 6, 7, 8, 10, 15, 20, 25, and 35 μ g of streptomycin were prepared as described by Foigacs and Kuceira,¹ with the exception that serum was substituted for oxalated blood. Agar plates were seeded with *B. subtilis* as in the original method.¹ The serum-streptomycin mixture was drawn up into a 0.1 ml serologic pipette with the aid of a Guthrie pipette controller.† The meniscus was lowered to one of the graduations, and the tip was wiped dry. By careful turning of the pipette controller screw, 0.1 ml was forced onto the pipette tip and touched to the agar plate which was resting on a level surface. This was repeated on each of five plates. There is space on each plate for four zones, so that each set of five plates was used for four different concentrations. The plates were incubated overnight at 30° C. The diameters of the zones of inhibition were then read with a millimeter rule. The mean of the five readings for each concentration was recorded. This procedure was carried out on thirty individual sera. The mean value for each point was obtained and plotted against micrograms of streptomycin, as shown in Fig. 1.

The statistical data are listed in Table I. At only two points, namely 3 and 15 μ g per milliliter, did the number of observations falling outside the

range of mean $\pm 2\sigma$ exceed 5 per cent. Sera from all age groups (newborn to adult) were used, and no significant difference between sera was found. Thus a master standard curve such as this can be used for all determinations.

Fig. 1.—Standard curve computed from thirty sera.

35	21	23.8—25.2	24.5	38	0

Determination of Serum Streptomycin Level—Capillary blood is collected. The collecting tube is made either from a three inch length of glass tubing with one end sealed, or from a 75 by 95 mm shell vial. The open end is drawn out to a capillary tip and sealed. The wide portion of the tube is held over the flame and an aneurysm is quickly produced in the softened glass by the expanding air within the sealed tube. For the collection of blood the capillary tip is broken off near its base. The finger or heel is punctured so that a free flow of blood is obtained. The tube is held in a nearly vertical position as possible and the blood readily flows into the tube and down to the base. For each determination 0.3 ml. or a 1.5 cm. column of blood is adequate. The tubes are stood upright until the blood is clotted, then the tube is filed off just above the surface of the blood. The clot is broken up with an applicator stick and the tube is centrifuged at 1500 to 2000 revolutions per minute for fifteen minutes. As

described, 0.5 ml serum is then drawn up into a 0.1 ml pipette and a drop of 0.1 ml is applied to each of five prepared plates. The plates are incubated overnight at 30° C. The mean of the five zones is converted to micrograms of streptomycin by means of the standard curve.

Fig 2—Chart showing expected variations in streptomycin values determined from given zone diameters. Solid curve represents the standard curve as in Fig 1. Dotted curves represent value of the mean ± 2 standard deviations and the mean -2 standard deviations. Vertical lines represent the range of zone diameter means obtained at each serum concentration of streptomycin. There are very few determinations falling outside the range of ± 2 standard deviations.

Fig 2 is a graphic representation of the range of error to be anticipated in the method. Rarely does the spread of observations exceed the range of 2 standard deviations. It can be seen that the least variation in estimated streptomycin level for a given zone diameter is to be found in that portion of the curve from 2 to 6 μ g of streptomycin, where for clinical purposes the least deviation is desirable.

For good results, the following precautions should be observed:

- (1) Media must be prepared with meticulous constancy, for slight variations in ingredients may markedly affect the activity of streptomycin.
- (2) The pH of the medium must be adjusted to 7.2 shortly before the plates are poured.

- (3) Results are best when flat-bottomed Petri dishes are used*. It is important that the 10 ml of medium be measured carefully when plates are poured.

- (4) Since dust particles distort the drops of serum, the room should be dust-free during the entire procedure.

- (5) The spore suspension is remarkably stable and is usually reliable for several months. However, it may become contaminated, with a resulting change in sensitivity. If this method is being used routinely over a long period of time, it is well to run a weekly or fortnightly standard curve to insure reproducibility.

Even with the increased variation at higher levels, the method is sufficiently exact for clinical purposes. It must be pointed out, however, that without modifications the method is not reliable for use in a patient receiving both penicillin and streptomycin, since the strain of *B. subtilis* used is moderately sensitive to penicillin.

*Pressed glass Petri dishes were obtained from Corning Glass Company, Corning, N. Y.

SUMMARY

A method is described for estimating streptomycin in serum. It uses only 0.3 ml. of blood, and therefore is particularly applicable for use among infants and children. It requires no unusual or expensive equipment and the laboratory techniques are easily acquired and carried out.

A METHOD FOR THE QUANTITATIVE DETERMINATION OF BILIRUBIN IN URINE

WALTER R. C. GOLDEN, PH.D. AND JOHN G. SNAVELY, M.D.
STAMFORD, CONN.

SEVERAL procedures for the quantitative determination of bilirubin in urine have been described. Most of these have utilized the principle of adsorption of bilirubin from urine on insoluble barium or calcium salts. Bilirubin is eluted from the adsorbate and some characteristic color reaction is used to determine the concentration. Methods employing these principles have been described by Hunter,¹ Godfried,² and With³ among others.

Our efforts to use such techniques for the quantitative determination of bilirubin proved disappointing for several reasons.

First, we were unable to effect complete removal of bilirubin from icteric urine. Pure bilirubin added to normal urine could be removed completely from solution by addition of barium chloride and centrifugation of the adsorbate, but quantitative removal of naturally occurring bilirubin from icteric urine could not be achieved by the same technique.

Second, elution of bilirubin from the barium sulfate bilirubin complex was incomplete after centrifugation.

Finally, the most disturbing problem arose in connection with the color development of the eluted bilirubin. The previously mentioned authors employed some modification of the Ehrlich diazo reaction. This reaction gives a characteristic red color with bilirubin. On diazotization, many urines develop a reddish brown color which masks the color of diazotized bilirubin. With³ tried to overcome this difficulty by extraction of the diazotized bilirubin with chloroform, but he reported that he was unsuccessful in obtaining quantitative extraction.

Some investigators have tried to estimate bilirubin in urine by direct diazotization without preliminary adsorption. Goodson and Sheard⁴ have published such a procedure. In their procedure no means of obviating the interference due to the diazotizable nonbilirubin chromogenic material in urine is offered.

Our attempts to determine bilirubin in urine by direct diazotization in simple alcoholic solution gave promising results when highly icteric urine was tested. However, normal dark urines free from bilirubin developed a red brown color upon diazotization. This red-brown color absorbed a significant amount of light when read in a photometer at a wave length suitable for diazotized bilirubin. A direct diazotization method, therefore, seemed to require some means of avoiding the interference of this diazotizable nonbilirubin chromogenic material.

It seemed feasible to avoid this interference by application of the Vierordt principle⁵ for determining individual concentrations of pigments in a mixture. This requires that the mixture be read at two wave lengths that the ratios of the optical densities at both wave lengths for each pigment in pure solution be known and that these ratios be constant over the range of concentrations to be tested. Gibson and Evelyn⁶ have applied this principle to the photometric determination of Evans blue in serum in the presence of hemoglobin. Engstrom and Mason and others have employed it for the photometric determination of 17 ketosteroids in urine.

Employing this principle we have developed a procedure for the determination of bilirubin in urine which overcomes interference from nonbilirubin materials.

Reagents —

METHOD

(1) Alcohol 95 per cent ethanol U.S.P.

(2) Diazo reagent A. Dissolve 1 Gm sulfanilic acid in 10 ml concentrated hydrochloric acid in a liter volumetric flask and dilute to mark with water (keeps indefinitely).

Diazo reagent B. Dissolve 0.5 Gm sodium nitrite chemically pure in water and make to 100 milliliters. Store solution in refrigerator and discard when it develops discernible color.

Diazo reagent for use. Mix fresh prior to determination 10 ml diazo reagent A and 0.3 ml diazo reagent B.

Procedure — One milliliter of urine (as voided or diluted*) is measured into a colorimeter tube (19 by 150 mm). Eight milliliters of alcohol and 1 ml of freshly prepared diazo reagent are successively added. Mix. Allow thirty minutes for color development then add 0.25 ml concentrated hydrochloric acid and mix. Read per cent transmission in photometer† at wave lengths of 575 and 450 m μ with photometer adjusted to read 100 per cent transmission with alcohol blank at each respective wave length.

Convert the transmission readings at each wave length to corresponding optical densities.

Optical density equals 2 minus log T where T equals per cent transmission. The optical density of bilirubin is then calculated from the equation $Y_{75} = 1.05 M_{450} - 0.202 M_{575}$ where Y_{75} equals optical density of bilirubin at 575 m μ , M_{75} equals observed optical density of diazotized urine at 575 m μ , M_{450} equals observed optical density of diazotized urine at 450 m μ and where the numerical constants have been derived experimentally as given elsewhere in the text.

Given Y_{75} the concentration of bilirubin equals K times Y_{75} where K is the calibration factor obtained as described below.

Standardization With Pure Bilirubin —

Stock standard (10 mg per cent). Dissolve 10 mg of pure bilirubin‡ in chloroform and make to a volume of 100 milliliters.

*In clinical testing the urine is diluted to 100 ml per hour if the urine flow is not already greater than that.

†Photometer readings are made on the Coleman Jr. Clinical Spectrophotometer model 6A.

‡Eastman Kodak Bilirubin No. 101.

Dilute standard (1 mg per cent) Dilute 10 ml of the stock standard to 100 ml with alcohol Measure 0.5, 1, 2, 3, 4, and 5 ml of the 1 mg per cent standard into colorimeter tubes These tubes correspond respectively to 0.5, 1, 2, 3, 4, and 5 mg per cent Make each to a volume of 8 ml with alcohol Add 1 ml of water to each and mix To each add 1 ml diazo reagent, mix, allow color to develop thirty minutes, then add 0.25 ml concentrated hydrochloric acid Mix and read at 575 m μ against alcohol blank set at 100 per cent transmission A transmission-concentration curve may be plotted on semilog paper or a conversion factor may be calculated from the corresponding optical densities according to the formula $K = \frac{C}{D}$ (where K is the conversion factor C is concentration in milligrams per cent and D is optical density) for that range of concentration where K is constant

Standardization performed in the preceding manner has yielded a K value of 6.2 for concentrations up to 5 mg per cent of bilirubin Thus, Y_s , times 6.2 equals concentration of bilirubin in milligrams per cent

SPECTROPHOTOMETRIC STUDIES

In the development of the method, certain spectrophotometric studies were carried out Bilirubin solutions, icteric urine, and normal urine were treated according to the described method with certain variations which will be noted The spectral transmittance curves were then determined * They are reproduced in Figs 1 to 3

The preparation of the material for the study was made as follows

Preparation 1 Bilirubin solution (equivalent to 2 mg per cent in urine) treated with diazo reagent and not subsequently acidified (*Curve 1*, Fig 1)

Preparation 2 Bilirubin solution (same as in Preparation 1) treated with diazo reagent and then acidified (*Curve 2*, Fig 1)

Preparation 3 Normal urine treated with diazo blank† and not subsequently acidified (*Curve 3*, Fig 2)

Preparation 4 Normal urine treated with diazo reagent and not subsequently acidified (*Curve 4*, Fig 2)

Preparation 5 Normal urine treated with diazo blank† and then acidified (*Curve 5*, Fig 2)

Preparation 6 Normal urine treated with diazo reagent and then acidified (*Curve 6*, Fig 2)

Preparation 7 Icteric urine treated with diazo blank† and not subsequently acidified (*Curve 7*, Fig 3)

Preparation 8 Icteric urine treated with diazo reagent and not subsequently acidified (*Curve 8*, Fig 3)

Preparation 9 Icteric urine treated with diazo blank† and then acidified (*Curve 9*, Fig 3)

*On a General Electric recording spectrophotometer at the Stamford Research Laboratories of the American Cyanamid Co

†Hydrochloric acid 15 per cent (15 ml concentrated hydrochloric acid in 100 ml solution)

Preparation 9 Icteric urine treated with diazo blank† and then acidified (Curve 10, Fig 3)

Curve 1 represents the spectral transmittance of the red (nonacidified) azobilrubin, the derivative commonly employed for quantitative bilirubin determinations in serum. This red pigment has its absorption maximum at 530 to 540 millimicrons. If the red azobilrubin is strongly acidified with hydrochloric acid, it is at once converted to a purple pigment*. Curve 2 shows the spectral transmittance of this pigment. The purple (acidified) azobilrubin has

Fig 1

its absorption maximum at 570 to 580 millimicrons. Since Curves 1 and 2 represent equal amounts of bilirubin it is seen that the purple pigment absorbs more light at 575 $m\mu$ than the red pigment at 530 millimicrons. This alone suggests that the purple (acidified) azobilrubin is the more sensitive derivative for photometric analysis.

Fig 2 presents the curves obtained using normal urine presumably bilirubin free. Curve 4 shows the transmittance of a pigment developed by diazotization and Curve 6 shows the change in transmittance produced upon acidification. Curve 3 is the blank for Curve 4 and Curve 5 is the blank for Curve 6.

Curve 4 has no maximum absorption band in the visible spectrum while Curve 6 has a broad maximum absorption band from 440 to 480 millimicrons. Both preparations show significant absorption at the wave lengths at which azobilrubin may be read that is 530 $m\mu$ for the red or 575 $m\mu$ for the purple pigment. The presence of the interfering substances in normal urine clearly indicates the need for a means of correction in methods employing direct diazotization. For convenience we designate this interfering material as a chromogen.

† The conversion of red azobilrubin to a purple pigment by acidification with hydrochloric acid has been known for some time and is in fact, attributed to both Ehrlich and Proscher (original reference not available) as cited by Müller.

Fig 3 presents the transmittance curves of icteric urine treated similarly to the normal urines of Fig 2. Curve 8 represents the transmittance characteristics of red azobilinubin modified by the presence of the unacidified diazo-

Fig 2

Fig 3

tized λ -chromogen. This shows a shift of the absorption maximum from 430 to 540 $m\mu$ for pure bilirubin (Curve 1, Fig 1) to 490 to 530 millimicrons. This curve is smooth since λ -chromogen has no absorption maximum in the visible

spectrum Curve 7 is the blank for Curve 8. Curve 10 presents the transmittance characteristics of purple (acidified) azobilirubin (Curve 2 Fig. 1) modified by the presence of acidified diazotized x chromogen. Curve 10 shows that the absorption maximum is neither shifted nor significantly broadened but there is a distinct depression in the otherwise smooth curve at 490 to 510 $m\mu$ apparently the effect of the absorption due to acidified diazotized x chromogen. These properties emphasize the superiority of the purple (acidified) azobilirubin for photometric analysis. Curve 9 is the blank for Curve 10.

DERIVATION AND APPLICATION OF CORRECTION EQUATION

The general form of the equation which applies for the photometric determination of the individual pigments of a two component mixture is derived as follows

- Let X = optical density of X substance at wave length a
 X_b = optical density of X substance at wave length b
 Y = optical density of Y substance at wave length a
 Y_b = optical density of Y substance at wave length b
 M = optical density of a mixture of X and Y at wave length a
 M_b = optical density of a mixture of X and Y at wave length b

$$(1) R = \frac{X}{X_b}$$

$$(2) R_r = \frac{Y}{Y_b}$$

If substances X and Y do not react chemically with one another the following holds

$$(3) M = X + Y$$

$$(4) M_b = X_b + Y_b$$

From (2) and (3)

$$(5) M = X + R_r Y$$

And from (1) and (4)

$$(6) M_b = \frac{X}{R} + Y$$

Solving equations (5) and (6) for Y_b we obtain

$$(7) Y_b = \frac{R M_b - M}{R - R_r}$$

An inspection of the spectral transmittance curves in Figs. 1 to 3 indicates two suitable wave lengths, i.e. 575 and 450 millimicrons. If we let Y represent bilirubin, X, the interfering x chromogen at 450 $m\mu$, and b 575 $m\mu$, then equation (7) can be rewritten

$$(8) Y_b = \frac{R M - M_{450}}{R - R_x}$$

To apply the formula for use the numerical values of R_x and R_r at 450 and 575 $m\mu$ must be derived. Values for R_x were obtained by diazotizing normal bilirubin free urines by the method given previously and finding the optical densities at 450 and 575 millimicrons

$$R = \frac{X_a}{X_b} = \frac{\text{optical density of x chromogen at 450 } m\mu}{\text{optical density of x chromogen at 575 } m\mu}$$

* ΔY : The computed minus the expected optical density of the added amount of bilirubin that is column four minus column five.

Summary of data in Table II. Mean deviation ($\Delta Y_{1.0}$) regardless of sign 00.5 mg per cent. Average per cent recovery of added bilirubin 99.7 per cent.

Values for R_x were similarly determined with pure bilirubin solutions. Table I shows the summarized data for the determinations of R_x and R_y .

Since $R_x = 5.19$ and $R_y = 0.25$ substitution of these values in equation (8) gives the final equation

$$(9) \quad Y_{75} = \frac{5.19 M - M}{5.19 - .25} = 1.05 M_{75} - .202 M_{450}$$

where Y_{75} equals the optical density of the bilirubin component of the mixture at 575 $m\mu$, M equals the optical density of the mixture of bilirubin and urobilinogen at 575 $m\mu$ and M_{450} equals the optical density of the same mixture at 450 millimicrons.

To determine the reliability of the equation and the method recoveries of bilirubin added to normal (bilirubin free) urine were carried out. The computed optical densities in these mixtures (Y_{75}) were compared with the optical densities of the same amounts of pure bilirubin determined simultaneously. Since precise amounts of bilirubin cannot be added conveniently to urine directly, the additions were accomplished by dissolving the desired amount of bilirubin in the alcohol used as the diluent in the method.

Table II presents a summary of these data.

The differences between the calculated and expected optical densities (Y_{75} of Table II) were small and were random with respect to sign. The average recovery was 99.7 per cent. We conclude that equation (9) introduces no significant theoretical error and is therefore valid and applicable for the calculation of the optical density of bilirubin mixed with urobilinogen according to our method.

The arithmetic mean of the optical density differences (column six Table II) was 0.0075 regardless of sign and this optical density is equivalent to approximately 0.04 mg per cent of bilirubin. An error of this order of magnitude is of little significance.

In order to show the order of magnitude of urobilinogen we have presented in Table III data obtained from a representative group of icteric urines. These results show that urobilinogen was encountered in all of

$Y_{75} = M_2 - Y_{12}$

† computed from equation (9)

these specimens and in amounts accounting for from 8 to 65 per cent of the observed optical density at 575 millimicrons. It is evident from the data that the correction for λ -chromogen is essential for the true bilirubin values.

MISCELLANEOUS DETAILS OF TECHNIQUE

Certain points of technique were investigated to determine conditions for optimum color development and reproducibility. The choice of alcohol as a diluent was based on the fact that the substitution of water for 95 per cent ethanol in the described method results in a diminution of optical density of diazotized icteric urine at both 450 and 575 millimicrons. An example is given in Table IV.

TABLE IV WATER VS 95 PER CENT ETHANOL AS THE DILUENT

DILUENT	OPTICAL DENSITY	
	575 m μ	450 m μ
Distilled water	268	168
95% Ethanol	337	252

The prescribed order of addition of reagents was found superior to other orders tried. Data in Table V show that each modification resulted in reduction of optical density at 575 millimicrons.

In the described method, thirty minutes are allowed for color development before the addition of acid because the color reaction changes little after

TABLE V ORDER OF ADDITION OF REAGENTS

ORDER OF ADDITION	OPTICAL DENSITY (575 m μ)		
	SOLUTION 1	SOLUTION 2	SOLUTION 3
1, 2, 3, 4, 5	350	--	--
1, 3, 4, 2, 5	310	--	--
1, 2, 3, 4, 5	--	314	633

- 2 95 per cent ethanol
- 3 Diazo reagent.
- 4 Color development period (thirty minutes)
- 5 Concentrated hydrochloric acid 0.25 milliliter

twenty-five minutes and is maximal at thirty minutes. Although the purple (acidified) azobilirubin is quite stable, there is no advantage in delaying the reading. The data concerning the rate of color development and the stability of the color are shown in Table VI. Pure bilirubin was used for these determinations.

*Acid added thirty minutes after diazo reagent.

In order to avoid variations due to rate of urine flow and to obviate turbidities in concentrated specimens it was found desirable to collect the urine over a timed period. The urine is then diluted to a total volume equal to 100 ml per hour. After mixing 1 ml of this diluted specimen is used for analysis. This dilution obviates turbidities and makes milligrams per 100 ml equivalent to milligrams per hour. For urine flow above 100 ml per hour appropriate correction must be made if the results are to be expressed in units of time. If the urine is turbid even after this dilution a portion should be centrifuged before taking the 1 ml for analysis. Highly retentive urines will require even greater dilutions than 100 ml per hour. Correction must be made for the further dilution in calculating the concentration of bilirubin or for expressing the amount of bilirubin per unit time.

Collection of specimens in stoppered brown bottles and prompt analysis are recommended to avoid loss of bilirubin as reported by With³. We have found losses of 14, 15, and 50 per cent of bilirubin from three retentive urine specimens held twenty-four hours in the refrigerator in stoppered brown bottles.

INTERFERING MATERIALS

We have investigated the possible interference with the procedure by certain common medications. Urine specimens were collected from patients receiving Solu B* and penicillin. Neither of these substances was found to have interfering properties as shown by the χ^2 values presented in Table VII Groups I and II.

Sulfathiazole and sulfadiazine in amounts of 25 mg. per cent do not interfere with the test as shown by the χ^2 values in Table VII Group III.

TABLE VII EFFECT OF MISCELLANEOUS MEDICATIONS

	Same urine + 3 mg. % Atabrine	215	047		- .008

Range of error expressed as bilirubin - .06 to + 0 mg. per cent

1: expected none

This proprietary vitamin B complex for parenteral use contains thiamine, riboflavin, pyridoxine, pantothenate and nicotinamide.

Atabine (quinacrine hydrochloride in amounts of 1, 2, and 3 mg per cent) shows a slight interference as demonstrated in the data of Table VII, Group IV. The 3 mg per cent concentration would mask approximately 0.05 mg per cent of bilirubin, an amount we consider insignificant.

Protein in the urine in amounts greater than 0.1 mg per cent (2 plus ring or acetic acid heat test) causes turbidities which render this method unsuitable. Since most of the commonly used protein precipitants may remove bilirubin with the protein, their use is contraindicated.

In the course of the derivation of the numerical value for R_x , a few urine specimens (four out of fifty-five) were encountered which gave R_x values exceeding the mean of 5.19 by about four times the standard deviation. It is safe to assume that these urine specimens contained some interfering material in addition to u-chromogen. Such an interfering material in a retentive urine would tend to mask a portion of the bilirubin. This effect was observed when two of these urine specimens were used for recovery experiments. In both instances the computed values of Y_{orange} were less than expected by an amount corresponding to approximately 0.2 mg per cent of bilirubin. We have been unable to identify the material responsible for this interference.

ADAPTATION OF METHOD TO FILTER PHOTOMETER

The method presented here would have limited clinical application if it could not be adapted to filter photometers. Its adaptation to one filter photometer was easily accomplished in our laboratory.*

Following the exact procedure outlined under Derivation and Application of Correction Equation, a group of ten normal urine specimens and a series of bilirubin solutions ranging from 0.5 to 4 mg per cent were diazotized and read in the Lumetron instrument using orange (580 $m\mu$) and blue (420 $m\mu$) filters. From these readings the constants R_x and R_y were calculated and found to be 8.0 and 0.31, respectively. Substituting these constants in equation (8), it becomes $(9_a) Y_{\text{orange}} = 1.04 M_{\text{orange}} - 0.13 M_{\text{blue}}$ where the symbols are analogous to those of equation (9) for the Coleman instrument.

Mean deviation regardless of sign 0.076

Range of error expressed as bilirubin - 0.08 to -0.11 mg per cent.

Average per cent recovery of added bilirubin 96 per cent.

*A Lumetron photometer model 400A was employed.

A calibration was carried out using the procedure outlined under Method A. A conversion factor (K) of 8.1 was obtained which was constant up to the 4 mg per cent concentration. Thus 8.1 times Y_{orange} equals milligrams per cent bilirubin.

The validity of equation (9a) was tested with mixtures of normal urine and bilirubin as described (Derivation and Application of Correction Equation). The data of this experiment are shown in Table VIII. The recoveries appear to be entirely satisfactory.

As an additional check on the reliability of the method using the filter photometer, a parallel series of determinations were done on icteric urine specimens using both instruments. The results show close agreement, as can be seen in the data of Table IX.

DISCUSSION

The method for the determination of bilirubin in urine which we have presented here is essentially a modification or adaptation of the Ehrlich diazo reaction as employed in the Malloy and Evelyn⁸ method for serum bilirubin. Since normal or icteric serum has no chromogen other than bilirubin which upon diazotization produces a significant amount of color with a spectral absorption maximum at 530 m μ , no separation of the bilirubin from the serum is necessary. This makes the determination in serum relatively simple and straightforward.

However, in normal or icteric urine there are amounts of chromogenic material which will react with the diazo reagent to cause a significant inter-

ference with the photometric reading of the diazotized bilirubin. Therefore in analyzing urine for bilirubin by this reaction one is faced with the necessity of (1) separating the bilirubin or its colored derivative from the urine by chemical or physical means, or (2) determining and applying a correction for the interfering material. Attempts at applying the first alternative have so far, to the best of our knowledge, proved unsuccessful. In the present work we have succeeded in employing the second alternative. The correction equation which we have derived was tested by adding known amounts of bilirubin to urine and obtaining satisfactory recoveries. This demonstrated to our satisfaction that neither significant theoretic nor systematic errors were encountered in the procedure.

We believe that we have enhanced the specificity and sensitivity of the determination by converting the red azobilirubin with spectral absorption maximum at $530\text{ m}\mu$ to the purple azobilirubin with spectral absorption maximum at $575\text{ m}\mu$ through acidification with hydrochloric acid. This has two beneficial effects. Our data show that in pure solution the red azobilirubin has less optical density at $530\text{ m}\mu$ than an equivalent amount of purple azobilirubin at 575 millimicrons . Thus small amounts of bilirubin can be determined more accurately as the purple derivative than as the red derivative. The second beneficial effect is that at $575\text{ m}\mu$ the interference of the nonbilirubin material which we have designated χ chromogen is significantly less than at 530 millimicrons . Even though the principle on which our correction equation is based would be equally valid for the readings at $530\text{ m}\mu$, nevertheless any means of minimizing the effect of the interfering material should be utilized.

With respect to the sensitivity of the method, we estimate a likely error of 0.15 in the computed values of Y_{575} . This is twice the mean error of our addition and recovery experiments (Table II). Such an error is equivalent to approximately 0.1 mg per cent of bilirubin in urine. In certain instances where two- or threefold dilutions of the urine have been made, the error might be as large as 0.2 to 0.3 mg per cent in terms of bilirubin concentration in the original urine. We feel that this is a liberal estimate of the lower limit of sensitivity of the method. In fact, repeated values of as little as 0.2 mg per hour have been found to date only in patients having disorders of bilirubin metabolism.

We believe that diazotization provides a more specific color reaction for bilirubin than oxidation methods using ferric salts or nitric acid as in the method of Singer and Kubin.¹ The red, blue, and green colored oxidation products are not too well characterized.

Finally, we wish to emphasize the relative simplicity of the procedure. It requires no special apparatus other than a reliable clinical photometer. The required reagents are readily available and easy to prepare. Once the correction equation and the standard curve or calibration factor have been determined for the instrument to be used, the routine performance of the test requires practically no more manipulation than a serum bilirubin determination.

SUMMARY

A method for the quantitative determination of bilirubin in urine is presented. It employs the principle of direct diazotization of urine with Ehrlich's diazo reagent.

A correction equation is derived and applied for the elimination of nonbilirubin interfering material.

A PRACTICAL METHOD FOR THE PREPARATION OF ORGANS FOR THE DETERMINATION OF ANTIBIOTIC CONTENT

B S SCHWARTZ, AND M N LEWIS
NEW YORK, N Y

IN THE course of our studies on penicillin tissue levels in small laboratory animals (rats and mice) we were faced with the problem of rapidly emulsifying a large number of organ samples under sterile conditions. The small tissue volumes, their large number, and the time and expense involved precluded the use of the semimicro Waring blender or of mortar and pestle.

We solved this problem by using a Foreedon Lighter Duty Flexible Shaft machine (approximately 1/25 horsepower), fitted with a wire brush, and 1/2, 1, and 2 ounce jars with metal screw caps (Fig 1). Holes just large enough to accommodate the shaft of the wire brush were made in the covers of the jars. The holes were plugged with cotton and the covered jars were sterilized. The tissues—lung, liver, kidney, and spleen—were removed aseptically and placed in jars appropriate to the volume of the sample. Two volumes of sterile 1 per cent phosphate buffer (pH 6.0) and some sterile aluminum were added. The sterilized wire brushes were inserted through the jar caps and attached to the handpiece. Rotation of the wire brush at approximately 10,000 revolutions per minute produced a finely ground tissue mash in about one minute. This mash was poured into centrifuge tubes and spun at low speed (500 to 1000 revolutions per minute), the clear supernatant liquid was used for assay. Used brushes were washed in 20 per cent NaOH to remove grit and tissue particles, rinsed in tap water, and resterilized.

Eighty to one hundred tissue samples, ranging from 0.5 to 30 Gm each, can be prepared satisfactorily in a single day by this method.

Fig 1

A RAPID METHOD FOR SERUM CALCIUM DETERMINATION

MAKIO MURAYAMA, M A
ANN ARBOR, MICH

IN MANY clinical situations, such as convulsions due to infantile tetany a rapid method for determination of serum calcium, even if somewhat less accurate, would be more valuable to clinicians than the time consuming standard method. A method to be most useful should possess speed and a reasonable degree of accuracy and require a minimum amount of blood.

The method to be described is a nephelometric procedure adapted from the one for determination of calcium in water.¹ Although less precise than a standard micro-method, the procedure can attain an accuracy adequate for the usual clinical purposes, it takes less than an hour and requires only 0.1 ml of serum.

Potassium oleate reagent in Duponol solution reacts with calcium ion in ammoniacal solution to give a white colloidal suspension of calcium oleate. The degree of turbidity is proportional to the amount of calcium present in trichloroacetic acid filtrate of serum. The turbidity is measured in a photoelectric colorimeter. The method described is adapted to Klett Summerson (micro) photoelectric colorimeter. Most of the common ions normally present in human serum have no effect on the reaction. Duponol prevents the formation of magnesium oleate, thus eliminating interference due to this ion.

REAGENTS AND APPARATUS

Potassium Oleate Reagent—This reagent is prepared as described by Safer and Clark.¹ Shake 7.05 Gm of oleic acid* with a solution of 1.60 Gm of potassium hydroxide in 50 ml of distilled water. Transfer the emulsion by means of 50 ml of 70 per cent ethanol to a flask. Reflux the mixture for one hour and dilute with distilled water to 250 ml in a volumetric flask.

Duponol Solution—Prepare 3 per cent solution in distilled water. Duponol P C is an emulsifying reagent †.

Potassium Oleate-Duponol Reagent—To each 100 ml of Duponol solution add 20 ml of potassium oleate reagent. Filter off, or remove by centrifugation, any sediment formed. This reagent is stable at room temperature but will come out of solution at lower temperatures. It can be brought back into solution by warming in an incubator at 37° C.

Twenty per cent Trichloroacetic Acid—Dissolve 10 Gm of pure trichloroacetic acid in distilled water and make up to 50 milliliters. It is not desirable

From the Department of Pediatrics and Communicable Diseases, University of Michigan.
Received for publication April 10 1948.

*Eastman Kodak Company, Rochester, N. Y.

†Sold by Dyestuffs Department of E. I. du Pont de Nemours and Company, Inc., Wilmington, Del.

to make more at a time because the solution is not completely stable. The solution must be kept in the refrigerator when not in use.

Calcium Standard Solution—Dissolve 0.5 gm of pure calcite (calcium carbonate) in a 500 ml Lallenmeyer flask with 20 ml of 1 N dilute hydrochloric acid, being careful to avoid spitting. Add about 200 ml of distilled water and boil for a few minutes to drive off the carbon dioxide. Cool to room temperature and transfer quantitatively to a 500 ml volumetric flask. Make up to volume with carbon dioxide free distilled water. Store in a glass stoppered bottle. This standard should be checked for exact calcium content using a permanganate titration procedure. Adjust the concentration of the standard to 40.0 mg of calcium per 100 milliliters.

Dilute Calcium Standard Solution—Dilute the preceding standard solution in 100 ml volumetric flasks. Add from a burette 10.0, 15.0, 20.0, 25.0 and 30.0 ml of the calcium standard solution and then add carbon dioxide free distilled water to the mark to get 4, 6, 8, 10 and 12 mg per 100 ml respectively.

Pipettes—Two types of pipettes are used in the method: the construction type,² modified to a larger volume and syringe pipettes,³ modified for semiautomatic delivery. The accuracy of a 1 ml syringe is about 0.01 per cent.⁴ The syringe pipettes⁵ are extraordinarily accurate and furthermore they are extremely convenient to handle. When the same volume of reagent is to be added to a number of samples these pipettes will save much time. On the other hand, they are not well suited for pipetting many different samples because the dead space of these pipettes requires a thorough cleaning between each sample. In this case the construction pipettes are more convenient. When the composition of the samples does not differ too much the washing of the pipettes can be neglected. The accuracy of a 1 ml construction pipette is about 0.1 per cent.⁶

The sizes of construction pipettes used are 0.5 ml and 1.3 milliliters.⁷ With syringe pipettes it is convenient to have pipettes in the sizes of 1 and 20 ml to deliver 0.5 and 10 ml respectively.

PROCEDURE

Deliver 0.5 ml of serum into a 12 ml Pyrex centrifuge tube. Add 10 ml of distilled water (with a 2 ml syringe pipette adjusted to deliver 10 ml). Then add 0.5 ml of 20 per cent trichloroacetic acid (with syringe pipette adjusted to deliver this amount). Mix the contents thoroughly with a paraffined wooden applicator and allow it to stand for five minutes. Centrifuge for ten minutes at 2500 revolutions per minute. Transfer 1.3 ml of centrifugate (with the construction pipette) into a calibrated colorimeter tube. Add 0.2 ml of concentrated ammonium hydroxide.⁸ Finally add 1 ml of potassium alkyl Diponol reagent (with a syringe pipette). Allow it to stand for fifteen minutes. Read the turbidity in a Klett Summerson (micro) photoelectric colorimeter.

² The syringe pipette frame may be obtained from Northon Tool and Instrument Company, Rushing, Pa. Construction pipette may be obtained from Arthur H. Thomas Company, Philadelphia.

³ Another 1 ml syringe pipette adjusted to deliver 10 ml is recommended as a check over

using a 420 (blue) filter * Set the zero against the distilled (as described in the Klett-Summeison manual) and then proceed. It has been found most expedient to construct the standard emulsion when a specimen is analyzed in order to keep error at a minimum. Prepare a series of dilute standard solutions of 6, 8, 10, and 12 mg of calcium exactly as the serum would be treated. Record the optical density of the unknown the same way, D_u . Convert the unknown optical density to milligrams of calcium per 100 ml of serum according to the equation

$$\text{Mg Ca per 100 ml of serum} = \frac{D_u}{D_s} \times \text{Mg Ca per 100 ml of standard}$$

EXPERIMENTAL

Saifer and Clark have investigated various conditions necessary for oleate formation for the determination of calcium in water. The conditions were studied in this laboratory to insure optimum conditions for calcium oleate formation with trichloroacetic acid filtrate.

Effect of Variation of Potassium Oleate Reagent—To 13 ml of trichloroacetic acid centrifugate were added 0.5, 1.0, 1.5, and 2.0 ml of potassium oleate-Duponol reagent, respectively. One milliliter was found to be the adequate amount to obtain the maximum optical density.

Effect of Variation of Ammonium Hydroxide—To 13 ml of trichloroacetic acid centrifugate were added varying amounts of concentrated ammonia. Then 1.0 ml of potassium oleate-Duponol reagent was added. Optical densities observed remained the same from 50 c mm of concentration up to 320 cubic millimeters. However there was a decrease in optical densities observed when 640 c mm or more of ammonium hydroxide was added.

Effect of Variation of Time—The reaction seems to take place instantaneously. However it has been found that a slight increase in turbidity takes place from fifteen minutes to thirty minutes, hereafter the turbidity is almost unchanged.

Precision of the Method—The results of ten analyses on one sample of human serum are shown in Table I. The average value is 9.6 mg. of calcium per 100 ml., and the maximum deviation from the average is 0.5 mg. per 100 milliliters.

TABLE II DETERMINATION OF ADDED CALCIUM TO POOLED SERUM

SERUM	KRAMER TRISDALL (MACROMETHOD) 20 ML. (MG PER 100 ML.)	RECOVERY	NEPHELOMETRIC 0.5 ML. (MG PER 100 ML.)	RECOVERY
S	10.1		10.4	
S + 3.9	14.1	40	13.8	34
T	10.3		10.7	
T + 3.9	13.8	35	14.1	34
U	9.9		10.3	
U + 3.9	13.6	37	14.1	8
V	10.8		9.6	
V + 3.6	14.1	33	12.9	3

Each determination shown is the average of triplicate.

The Extent of Recovery—The average recovery for the three experiments when 3.9 mg. of calcium were added to 100 ml. of serum was 37 for the Kramer Trisdall method and 35 mg. per 100 ml. of serum for the nephelometric method. In the case of 3.6 mg. per 100 ml. of serum the recoveries were 33 and 33 mg. per 100 ml. for both the Kramer Trisdall and the nephelometric methods.

Relationship of Concentration to Optical Density—Nephelometric measurements are carried out by the same procedure and instruments used for the measurements of substances in solution, that is by comparison against a series of standards. Transmittance measurement particularly when used in instruments equipped with a photoelectric cell is the most sensitive and satisfactory. For the procedure described, it has been found that optical density is directly proportional to concentration and thus resembles optical density for substances in solution. Therefore in this method turbidity measurement is carried out and results are calculated in the same manner as for light absorption.

SUMMARY

A rapid method for the determination of serum calcium has been presented. It is possible to obtain the results in an hour on a duplicate sample of 0.5 milliliter. The results have been found to be adequate for clinical purposes.

CIRCULATION TIME AN ACCURATE INDICATOR FOR OBJECTIVE MEASUREMENT

BERNARD J MILLER, M D
PHILADELPHIA, PA

MANY methods for measuring the velocity of blood have been proposed in recent years. Despite this, there are few that are simple to perform and dependable with reference to accurate reduplication of measurement.

The response to the particular substance used may be subjective, such as the sensation of heat,^{1,3} neuromuscular stimulation,⁴ or taste,⁵ while objective responses may be manifested by their color^{8,9} radioactivity,¹¹ or fluorescence.¹¹ Obviously any method depending upon the patients' perception is subject to uncontrollable factors which modify the accuracy and consequently the clinical value of the determination. In addition such procedures are not applicable to the unconscious patient.

During the course of clinical investigations of the state of the circulation in surgical patients with the dye T1824, the arrival of the dye in the vessels of the ear was first studied with the Millikan oximeter.¹² The galvanometer deflection with this instrument was not sufficiently rapid for circulation time measurement, nor was the deflection of sufficient magnitude to produce an unmistakable end point. The photometer to be described gives improved response and deflection. Stability is sufficient to permit valid recording of the changing optical density of T1824 over a considerable period of time. Studies of the mixing time of T1824, using this method, will be reported in a later communication.

The principle involved depends upon the measurement of light intensities which have been adequately filtered to insure relative monochromacy. There are three essential components to the apparatus, namely a stable light source and screening filter which transmit light in the vicinity of 6200 Å, a photocell and direct coupled amplifier of high sensitivity and good stability, and an indicating galvanometer or graphic recorder.

APPARATUS

Light Source—The light source is mounted at one end of the ear piece (4, Fig 1) and utilizes a 6 to 8 volt bulb (Mazda 50) operated at 55 volts. In addition to supplying the necessary light, the bulb also furnishes gentle heat which produces vasodilatation with consequent increase in both blood and dye thickness. This is desirable since an increase in dye thickness produces a reduction in monochromatic light intensity. The lamp current is maintained at a constant value by the introduction of the counter-cill (B2, Fig 2) and re-istat (Fig 2) connected across R7 (Fig 2). Voltage regulation is better than 0.25 per cent. A wet storage cell (D, Fig 1) is used to operate the light.

From the Department of Surgery and Surgical Research, Jefferson Medical College.
Received for publication April 26, 1948.

Fig 1—Apparatus for recording circulation time with TINS² 1 Light source E filter compartment C photocell compartment D storage battery for light source F mirror galvanometer k Esterline Angus graphic recording meter G direct coupled amplifier

Light Filter—The screening filter is a composite unit consisting of two Corning glasses No 241b and No 9780. The exact spectral transmission is measured with a spectrophotometer lies between 5880Å and 6000Å with 100 per cent transmission at 6100Å and 80 per cent at 6200Å. The filter is placed in the compartment (B Fig 1) in front of the photocell and completely screens all light passing through the ear to the photo cell.

Photocell—Photronic cells were not considered applicable because of their inherent instability and sensitivity to infrared light.¹³ In addition the output of photonic cell is insufficient for recording low values of light intensity with relatively rugged instrument. The photoemissive type of cell RCA No 9.6 was found to be completely suitable because of its spectral response, small size and stability. Adequate light and capacity handling are provided by means of a small metal cylinder which is securely fastened to the frame of the ear piece (C Fig 1). The light aperture is 1 mm in diameter. The photocell is connected to the amplifier by means of a high insulation shielded cable and coaxial connector. An anode potential of 7.5 to 10 volts will not produce ionization of the residual gas in the photocell. The response to minute changes in light intensity is instantaneous.

Amplifier—In order to obtain maximum sensitivity plus large response from a photo tube it is necessary that the grid current of the measuring tube be in the vicinity of 10-32 amperes. Grid current in measuring tubes places a lower limit on the current sensitivity. These characteristics may be obtained in specially designed electrometer tubes or in acorn tubes operated under special conditions. Grubbs and Poole¹⁴ and recently Naei¹⁵ have shown that acorn tubes may be operated with grid current comparable to that

*Light filter No 60 obtained from Rubicon Company Philadelphia Pa.

with a mirror galvanometer movement #3070 and a 12 inch light scale affords unmistakable reading of light intensity. The enclosed light source consists of a pen light type of bulb, a condensing lens, and a 1.5 volt dry battery. The shunt resistance is equal to the critical damping resistance of the movement. An Esterline Angus graphic recorder (Fig 1) with a 1 Ma movement may be used for continuous recording of optical density. Full scale deflection of the recorder is easily obtainable with the standard amount of light passing through an ear of normal thickness and the light filter.

A type RCA #959 acorn tube is used in the first stage. The grid input resistance is selected by means of switch *S5* (Fig 2). Surface leakage in the grid selector switch is reduced to a minimum by first treating the switch with DC 200† and fusing at a temperature of 400 C for at least two hours. The suppressor grid, G3 and control grid, G1 are reversed in position. The plate and screen are operated at 6 volts and the filaments at 0.8 volt. These reduced operating conditions improve stability and reduce grid current. A negative bias of 45 volts on the control grid G3 results in a linear response. The potential of Grid G1 is maintained at approximately 0.8 volt positive depending upon its effect on the slope and the linearity of the plate curve.

The second and third stage function as voltage and current amplifiers respectively. The output of the acorn tube RCA #959 is fed directly to the grid of an RCA #1N5. A negative bias of 45 volts is sufficient to control plate current. The screen grid and plate are both operated at 45 volts. An RCA #1C5 is used in the last stage with 45 volts applied to the screen and 225 volts to the plate. A negative grid bias of 2.5 volts will permit cutoff operations in this stage.

An input resistance of 10^8 ohms will produce full scale deflection of the recording meter when the photocell receives light passing through an ear of normal thickness and the #690 filter. A 1 volt input signal will produce a 1 Ma increase in the plate current of the final stage.

The entire amplifier with the exception of the photocell is enclosed in a heavy aluminum cabinet (Fig 1). The tubes and input resistance are firmly supported on the metal panel by means of metal brackets and are further enclosed in an airtight plastic case containing anhydrous calcium chloride. This further reduces atmospheric effects on the surface resistance of the tubes and improves stability. All batteries with the exception of the 6 volt storage cell used for the light source are enclosed in the cabinet. The B batteries are of medium size since the current drain is minimal.

Operation—A double pole double throw switch permits the use of the internal galvanometer (MI Fig 2) together with the variable shunt (*R12* Fig 2) or an external indicating device. The amplifier is placed in operation by means of switch *S1* (Fig 2). A warm up of about five minutes is sufficient to insure stability. The bulb and bucking circuit (*B6* and *R11* Fig 2) are placed in operation by means of *S3* (Fig 2). The bucking circuit is necessary only if the indicating meter goes off scale when using the standard amount of illumination. Zero setting of the indicating galvanometer is determined by the position of *R4* (Fig 2). With the amplifier operating slightly above zero bias the inverse feedback control (*R3* Fig 2) is gradually rotated clockwise to the point where the meter deflection begins to decrease. This position indicates adequate locking of the input and output signals and effective feedback operation. Further adjustment of the inverse feedback and zero controls is not necessary. The condition of all batteries may be determined from the meter (MI Fig 2) by rotating switch *S4* (Fig 2).

METHOD

The amplifier is placed in operation. No adjustments of zero or feedback controls are necessary. The patient is placed in a recumbent position. The right arm is elevated to the approximate position of the right auricle.

†Rubicon Company
Liquid Dimethylsilicone DC 60 supplied by the Dow Corning Corporation Midland Mich

Fig 3—Graphic measurement of arm-to ear circulation time using 20 mg. of T1821

and the ear piece is applied to the right ear. There is no need for warning the patient about any sudden reaction. Illumination is next applied to the ear. The galvanometer deflection will decrease slightly within the next few minutes and then come to rest. This is due to increasing vasodilatation. Full scale deflection is next obtained by means of a potentiometer placed in the output circuit. An 18 gauge needle is then inserted into the antecubital vein of the right arm and after a short pause approximately 3 cc. of the dye* are

*0.5 per cent sterile solution of T1821 supplied by William Warner Company N. Y.

rapidly injected. A stop watch may be used to determine the time interval, to the nearest 0.5 second between the moment of injection and the beginning of galvanometer deflection.

Some slight difficulty may be encountered in differentiating the beginning of galvanometer deflection from the steady fluctuation of the galvanometer due to respiration. The error in this regard is of no clinical significance since it is always below 0.5 second. This difficulty is eliminated by using a graphic recorder. If a recording meter is used the time interval may be determined by measuring the time base (Fig. 3). Circulation time measurements may be made to 0.1 second with this method. The determination may be repeated if desired.

OBSERVATIONS

A series of circulation time measurements using T1824 was made on a group of eighteen patients who did not exhibit any clinical evidence of congestive heart disease. In addition repeat measurements were made within fifteen minutes using smaller quantities of dye (Table I). These values were then compared with those obtained with a standard clinical procedure using calcium gluconate.

Circulation time measurements with T1824 varied between 10.0 and 21.0 seconds, with an average of 14.2 seconds. In one instance both initial and repeat determinations revealed a circulation time of 21.0 seconds. This was observed in a 68 year old emaciated white male patient. Two sets of determinations were obtained in Negro patients. In these instances the galvanometer deflection was reduced but was still within adequate range to reveal a sharp end point. The greatest difference between repeat measurements was 2.0 seconds (Table I).

Measurement of the circulation time with calcium gluconate varied between 12.0 and 25.0 seconds with an average of 18.0 seconds. In three instances the patients were confused in relation to the moment of heat sensation in the pharynx. The difference between the average circulation time obtained with T1824 and that obtained with calcium gluconate for each individual varied between 0.8 and 6.5 seconds.

DISCUSSION

Circulation time measurements obtained with T1824 are in general agreement with those reported for methods using various chemical substances. Goldberg¹ using calcium gluconate reported normal circulation times between 10 and 16 seconds. Bernstein and Simpkins² reported an average of 12.9 seconds for circulation times with magnesium sulfate. Magnesium sulfate has the added advantages of producing a sharper end point and being less toxic than calcium gluconate.^{18, 19} Average circulation times in normal individuals of 20.8 seconds have been reported when papaverine was used.⁴ 12.9 seconds with alpha lobeline⁵ and 15.6 seconds with fluorescein.²¹ Circulation times measured with calcium gluconate were always longer than those obtained with T1824 in this study.

*Wratten relative filters obtained from Wratten & Pack Company, Inc. Boston, N. A.
 Calculated time in seconds from 1 frame 1 with 1 sec film - Anscombe's table for color film, 35 ft, 7

The differences observed between repeat measurements with T1824 were 20 seconds, or less, in all cases. A difference of 20 seconds was observed in two instances the remainder were within one second. Lihenfeld and Berliner²⁰ reported differences of 3 to 199 per cent in repeat determinations using alpha lobeline, with failure to obtain any reaction in 20 per cent of their patients. With papaverine differences in duplicate determinations have been as great as 3 seconds.*

SUMMARY

The azo dye T1824 may be used as an objective measure of circulation time. Inherent errors of subjective methods are eliminated and patients are not aware of any discomfort during the process of the test. The test may be performed in individuals having deeply pigmented skins with only slight sacrifice of galvanometer deflection.

The use of monochromatic light and a high sensitivity indicating apparatus permits detection of minute amounts of dye in the blood stream. Validity of circulation time measurements with T1824 is dependent upon the sensitivity and time constant of the amplifier. The amplifier described has a short time constant and high degree of sensitivity. Amplification is sufficient to produce galvanometer deflection as high as 10.4 centimeters. In addition provisions are made for continuous recording of dye concentration in the blood stream.

The author wishes to thank Dr. John H. Gibbon Jr., and Dr. Frank F. Allbritten Jr., for assisting in the preparation of this manuscript and Mr. Martin Miller for assistance and advice in the mechanical construction of this apparatus. The author also desires to acknowledge the technical assistance of Mr. Franz Goldstein and Miss Theresa D. Urso in the performance of circulation time measurements.

ANTIHYALURONIDASE ANTAGONISTIC TO PNEUMOCOCCUS HYALURONIDASE IN THE SERUM OF NORMAL HUMAN BEINGS AND PATIENTS WITH PNEUMOCOCCIC PNEUMONIA RISE OF TITER IN BACTEREMIC PNEUMOCOCCIC PNEUMONIA

ROBERT T. THOMPSON, M.D.
CINCINNATI, OHIO

THE problem of rapidly fatal pneumococcal pneumonia at the Cincinnati General Hospital has prompted the present inquiry into the pathogenesis of this disease. Approximately one fourth of the fatalities due to pneumococcal pneumonia at this hospital in the last three years occurred within twenty-four hours of the patient's admission.^{1,2} Between July 1, 1945 and July 1, 1947 there were 426 patients with pneumococcal pneumonia admitted including those with purulent complication on admission; the mortality has been 15 per cent.

In 1931, from a study of human autopsy specimens Loeschel³ concluded that actively advancing pneumococcal pneumonia spread within a lobe of lung by progression of a peripheral zone of edema fluid containing pneumococci from alveolus to alveolus through the pores of Kohn. This was corroborated experimentally by Robertson, Coggeshall and Terrell,⁴ Gunn and Nungester,⁵ and Wood.⁶ These investigators found that spreading experimental pneumococcal pneumonia was marked by a peripheral zone of alveoli containing fluid and pneumococci which preceded definite change in the appearance of the alveolar cells or the migration of erythrocytes and polymorphonuclear leucocytes into the alveoli. Robertson and associates⁴ also described regurgitation of this infected alveolar fluid through communicating bronchioles into previously uninvolved alveoli of the same lobe of lung. Robertson and Hamburger described the interlobar spread of experimental pneumococcal pneumonia by the intrabronchial flow of infected fluid exudate.

Filtrates of virulent cultures of pneumococcus contain spreading factor (diffusion factor) which produces edema when injected into the flank skin of the rabbit.⁸ This edema producing effect of spreading factor was demonstrated to be enzymic when Chain and Duthie¹⁴ established the identity of spreading factor and hyaluronidase in 1939. In a survey of *in vitro* hyaluronidase production by eighty-one strains of pneumococcus isolated from successive cases of pneumonia, Humphrey found no correlation between the amount of hyaluronidase produced and the clinical severity of pneumonia.¹⁷ However the *in vitro* production of hyaluronidase by pneumococci, which varies according to the availability of hyaluronic acid in the medium and the duration of incubation of the

This work was done in the Departments of Internal Medicine and Biochemistry of the College of Medicine of the University of Cincinnati and the Cincinnati General Hospital.

Received for publication March 5, 1948

culture, may not truly reflect the elaboration of hyaluronidase during pneumococcal infection. Therefore the present investigation was undertaken to study *in vivo* elaboration of hyaluronidase during pneumococcal pneumonia in man.

Spreading factor was first described by Duran-Reynals in 1928⁹ when the lesion of vaccinia infection of the rabbit was enlarged by aqueous extracts of rabbit, guinea pig, and rat testicle. The spreading effect was characterized by a zone of edema and was ascribed to an increase of tissue permeability by McClean¹⁰ and by Hoffman and Duran-Reynals.¹¹ Duran-Reynals found this spreading factor in filtrates of only invasive strains of staphylococci and streptococci and not in noninvasive strains.¹²

Hyaluronidase is the enzyme which hydrolyzes the viscous mucopolysaccharide called hyaluronic acid.¹³ Hyaluronic acid, the substrate, has been extracted from mammalian vitreous humor, synovial fluid, umbilical cord,¹³ and skin.¹⁴ There is indirect evidence of the presence of hyaluronic acid in lung tissue.¹⁷ Hyaluronic acid is soluble in water and will not dialyze through a porous cellophane membrane. The exact chemical composition of hyaluronic acid is undetermined, but it is known to contain equimolar amounts of hexosamine, acetyl, and glucuronic acid.¹⁵ Hyaluronic acid, the substrate, is not antigenic,¹⁶ in contradistinction to hyaluronidase, the enzyme, which is antigenic.²⁰ The studies of Bensley¹⁸ suggest that hyaluronic acid is one of the components of the intercellular ground substance of loose connective tissue. Accepting the probability of this premise, Duran-Reynals has proposed the hypothesis that infection by invasive bacteria is induced by hydrolysis of the mucoid ground substance of connective tissue.¹⁹

Hyaluronidases are antigenic, as demonstrated by McClean in 1943.²¹ Therefore it was proposed to estimate the amount of pneumococcus hyaluronidase elaborated in selected cases of pneumococcal pneumonia by titration of the corresponding antihyaluronidase which was elaborated in the serum of each patient. A series of sera was drawn on each patient tested and rises of antihyaluronidase titer in a given patient's series of sera were taken to indicate elaboration of hyaluronidase during that patient's infection.

Three groups of patients, representing three rather definite degrees of severity of primary pneumococcal pneumonia, were selected for these tests. Qualifications of the patients selected for the respective groups were as follows: Negative blood culture and no purulent complication, pneumococcus bacteremia and no purulent complication, and pneumococcus bacteremia with purulent complication. All of these patients were studied while they were under treatment for pneumonia at the Cincinnati General Hospital. All patients included here had blood culture taken on admission to the hospital, and initial serum was drawn within three days of admission.

A preliminary report of this work was published in abstract form in 1946,^{21*} and a later report was published in abstract form in 1947.^{22*}

*These reports were read at the 1945 and the 1947 Meetings of the Central Society for Clinical Research.

METHODS

Serial dilutions of the serum to be tested were incubated with a constant amount of hyaluronidase, and then these incubates were tested for residual hyaluronidase activity by Byers' modification²³ of McClean's mucoprotein clot prevention (MCP) test²⁰. The highest dilution of the serum which inactivated a constant amount of hyaluronidase was taken as the antihyaluronidase titer of that serum.

The hyaluronidases used in these tests were Seitz filtered seventy two hour cultures of mouse virulent Types 1, 2 and 7 pneumococci in fluid medium which contained 0.75 per cent potassium hyaluronate and no glucose. The potassium hyaluronate used was prepared by the method of Byers, Tytell and Logan²⁴. The three hyaluronidases used in the preliminary tests²¹ were prepared by Gibert in the semisynthetic medium which she developed for pneumococci²⁵. The three hyaluronidases used in subsequent tests were prepared in beef heart infusion broth (Difco). By the mucoprotein clot prevention test five of these hyaluronidases were active in the dilution of at least 1:16,000, and the sixth was active in the dilution of 1:1,200.

The constant amount of hyaluronidase used throughout these tests was 0.25 cc of the unrefined hyaluronidase which had been diluted so that a 1:8 or a 1:16 dilution prevented the mucoprotein clot, regardless of the original potency of the preparation used. This dilution of each hyaluronidase was freshly prepared each day and was used to supply all tests done that day. All dilutions of hyaluronidase and of serum to be tested were made in 1 per cent proteose peptone in physiologic saline. This solution minimized a partial loss of potency which occurred when the hyaluronidases were diluted in distilled water or physiologic saline.

All of the sera in one patient's series of sera were tested at one time with one hyaluronidase preparation. Five to seven normal sera and the serum of Patient A. T. * as the control were tested at one time with the Type 2 pneumococcus hyaluronidase. Twofold serial dilution beginning with 1:2 was made for each serum tested. Usually ten dilutions were made for each serum, but more were added as needed to obtain an end point. Serum dilutions were made in the volume of 0.5 cc in tubes 100 by 13 millimeters. The constant amount of hyaluronidase in the volume of 0.25 cc was added to each serum dilution and to a control tube containing 0.5 cc of proteose peptone saline with no serum. The tubes were mixed by shaking the tube rack then they were incubated at room temperature (25°C) for twenty minutes. The final dilution of serum in the first tube was 1:3 and the final volume in each tube was 0.75 cubic centimeter.

Residual hyaluronidase activity which remained after incubation of the serum dilution and hyaluronidase mixtures was determined as follows.

(1) To each tube was added 1.0 cc of substrate. This substrate contained equal volumes of three components: dialyzed tryptic digest of umbilical cord

* This patient was six months convalescent from Type 2 pneumococcus tricuspid endocarditis with repeated septic pulmonary emboli which were complicated by Type 2 pneumococcus empyema.

which contained approximately 0.20 per cent hyaluronic acid,²¹ normal horse serum which exhibited neither hyaluronidase nor antihyaluronidase activity, and distilled water.

(2) The tubes were mixed by shaking the tube rack. They were incubated in a water bath at 37° C. for thirty minutes, and then cooled in an ice water bath for five minutes.

(3) To each tube was added 1.0 c.c. of 5 per cent acetic acid, and each tube was shaken individually and read for formation of the mucoprotein clot. The highest dilution of a given serum which exhibited either heavy or thready clot was taken as the antihyaluronidase titer of that serum. Results were expressed in terms of dilution of serum prior to addition of the substrate. Activity of the constant amount of hyaluronidase was demonstrated in the control tube by prevention of the clot.

The mucoprotein clot prevention had a standard error of about 22 per cent as estimated by McClean in his own use of the test.²⁰ The determination of antihyaluronidase, as done here, permitted a twofold chance variation of titer of a given serum, but fourfold variation did not occur. For example, antihyaluronidase determinations were repeated eight times on the serum of Patient A T in its use as a control serum, with titers of 1:384 six times and titers of 1:192 two times.

TABLE I. ANTIHYALURONIDASE ANTAGONISTIC TO PNEUMOCOCCUS HYALURONIDASE (FROM TYPE 2 PNEUMOCOCCUS), SERUM TITERS OF NORMAL HUMAN BEINGS COMPARED WITH THE SERUM TITERS OF CONVALESCENT PATIENT A T*

†The highest dilution of the serum which inactivated the constant amount of hyaluronidase used in the test.

RESULTS

Normal Human Serum—Antihyaluronidase antagonistic to Type 2 pneumococcus hyaluronidase was present in the serum of two normal human beings in the same titer as that of Patient A. T four were $\frac{1}{2}$ the titer of Patient A. T ten were $\frac{1}{4}$, sixteen were $\frac{1}{8}$, seven were $\frac{1}{16}$, nine were $\frac{1}{32}$ and two were $\frac{1}{64}$ (Table I).

Serum of Pneumococcic Pneumonia Patients—Serial sera of twenty six patients with pneumonia were tested seven patients had negative blood culture and no purulent complication, eleven patients had pneumococcus bacteremia and no purulent complication eight patients had pneumococcus bacteremia with purulent complications.

Antihyaluronidase titers decreased

†This patient died on the fifteenth hospital day of left ventricular cardiac failure

Serum of Patients With Negative Blood Culture and no Purulent Complication—Antihyaluronidase responses obtained in the seven patients in this group are presented in Table II and Fig. 1 and the sequence of cases in Table II corresponds with the sequence of graphs in Fig. 1. The sera of two patients were titrated against Type 1, Type 2 and Type 7 pneumococcus hyaluronidases, sera of four patients were titrated against two of these hyaluronidases and sera of one patient were titrated against only one hyaluronidase. Changes of antihyaluronidase titer found in these fifteen titrations of serial sera were one fourth fold once, one half fold four times unchanged five times, and two fold five times. The abscissa of each graph represents the time in days subsequent to hospital admission at which serum samples were drawn from the patient. The ordinate represents the antihyaluronidase titers of the sera tested expressed as the reciprocal of the highest dilutions of sera which inactivated the constant amount of hyaluronidase. Each curve represents the antihyal

uronidase response as titrated against one of the hyaluronidases. From the graphs in Fig 1 it can be seen that none of these patients exhibited rise of serum antihyaluronidase titer which exceeded twofold, representing no rise within the accuracy of the test.

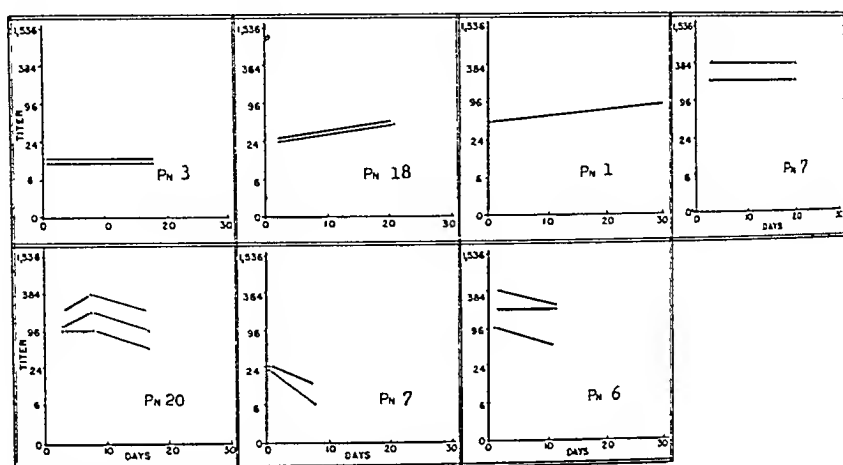

Fig 1—Antihyaluronidase in pneumococcal pneumonia, blood culture negative

The clinical data pertaining to these seven patients are shown in Table III. Their average age was 45.7 years. An average of 1.7 lobes was involved by pneumonia,* and the average hospital stay was 16.4 days. The only death occurred in a 72-year-old woman who died of left ventricular cardiac failure on her fifteenth hospital day, four days after roentgenogram had shown marked resolution of the pneumonia.

*Sulpha. Ordinary doses of sulfamerazine¹ or sulfadiazine units of amorphous penicillin every three hours intramuscularly. Penicillin 20,000 to 25 u. Serum type specific therapy.

†This patient died on the fifteenth hospital day of left ventricular cardiac failure.

Serum of Patients With Pneumococcus Bacteremia and no Purulent Complication. Antihyaluronidase responses obtained in the eleven patients in this group are presented in Table IV and Fig 2, and the sequence of cases in Table

*No distinction was made in this or the other groups of patients as to whether distribution of pneumonia was lobar or bronchial. The type of infecting pneumococcus was identified in all cases and the distribution of the pneumonia was identified by roentgenogram in all cases.

IV corresponds with the sequence of graphs in Fig 2. The sera were titrated against Type 1, Type 2, and Type 7 pneumococcus hyaluronidases. Rises of antihyaluronidase titer found in these thirty three titrations of serum sera were no change once, twofold seven times fourfold six times eightfold eleven times, and sixteen fold eight times. From the curves in Fig 2 it can be seen that the first eight patients exhibited rises of titer which were fourfold or greater and that six of these eight patients exhibited rises which were eightfold or greater. These increases of antihyaluronidase titer were all apparent during the patients' first week of hospitalization and were not specific for pneumococcus type. In four patients who were observed for more than thirty days the highest rise of serum antihyaluronidase titer occurred thirteen to thirty days after pneumococcus bacteremia. The last three patients in this group exhibited rises of titer which were twofold or less representing no rise within the accuracy of the test.

‡These complications occurred during convalescence.

Serum of Patients With Pneumococcus Bacteremia With Purulent Complications Antihyaluronidase responses obtained in the eight patients in this group are presented in Table VI and Fig. 3 and the sequence of cases in Table VI corresponds with the sequence of graphs in Fig. 3. The sera were titrated against Type 1, Type 2, and Type 7 pneumococcus hyaluronidases. Rises of antihyaluronidase titer found in these twenty four titrations of serial sera were fourfold six times eightfold five times sixteen fold three times thirty two fold

Fig. 3—Antihyaluronidase in pneumococcal pneumonia pneumococcus bacteremia with purulent complications

three times, and sixty four fold or greater seven times. From the curves in Fig. 3 it can be seen that all eight patients exhibited rises of titer which were four fold or greater, and that four patients exhibited increases which were eightfold or greater. Rises of antihyaluronidase titer in six patients were apparent during the first week of hospitalization and in all patients were not specific for type of pneumococcus. In five patients who were observed for more than thirty days the highest rise of serum antihyaluronidase titer occurred ten to twenty seven days after pneumococcus bacteremia.

The clinical data pertaining to these eight patients are shown in Table VII. The average age was 48.3 years. An average of 1.7 lobes was involved by pneumonia, and the average hospital stay was 41.0 days. The first six patients recovered, the seventh died of empyema on the twenty fifth hospital day and the eighth died of multiple lung abscesses on the thirty second hospital day.

Particular Considerations of the Antihyaluronidase in the Serum of Patients With Pneumococcal Pneumonia Studies which indicate that the antihyaluronidase in these sera was specifically antagonistic to hyaluronidase elaborated by the species pneumococcus have been reported elsewhere.⁹

*Sulfa, Ordinary doses of sulfamerazine[†] or sulfadiazine penicillin 20 000 to 20 000 units
of amorphous penicillin every three hours intramuscularly serum type specific therapy as
antipneumococcal rabbit serum (Lederle)

†This patient received intrapleural penicillin only

‡These patients died on the twenty-fifth and thirty-second hospital day respectively

Therapeutic antipneumococcal rabbit serum exhibited very little anti
hyaluronidase The highest dilution of Type 2 concentrated antipneumococcal
serum* which antagonized the constant amount of Type 2 pneumococcus hyal
uronidase was 1:12

*The antisera tested were Lederle Lot No 472H676J 50 000 units per vial, and Lot
Lot No B4555 20 000 units per vial

Intravenous administration of 200,000 units of Type 1 therapeutic anti pneumococcal rabbit serum (Lederle) in two injections to a patient with Type 1 pneumonia did not bring about an increase of the patient's serum antihyaluronidase titer in the two day period following the antiserum but did produce a marked rise in titer of agglutinin for the specific pneumococcus. There were no agglutinins for Type 1 pneumococcus before the antiserum but there was a progressive rise of agglutinin titer to 1:2560 (2 plus) as observed at four intervals in the two day period. One patient with Type 7 pneumonia who was given 200,000 units of Type 7 antipneumococcal rabbit serum intravenously in one injection exhibited no change of serum antihyaluronidase titer twenty days later.

High therapeutic concentrations of penicillin and sodium sulfadiazine did not exhibit antihyaluronidase activity when titrated against pneumococcus hyaluronidase. The concentrations tested were 4 units of penicillin per cubic centimeter (Food and Drug Administration Standard) and 20 mg per 100 cc of sodium sulfadiazine.

Low titer and high titer antihyaluronidase sera from one patient and sera from two other patients exhibited no loss of antihyaluronidase activity following one hour at 56° C in a water bath.

Patients with other pneumococcus infections without pneumonia exhibited rises of serum antihyaluronidase titer. One patient with pneumococcal meningitis secondary to mastoiditis and another patient with mesothelioma of the pleura complicated by pneumococcal empyema exhibited respectively fourfold and eightfold rises of serum antihyaluronidase titer as tested with the three pneumococcus hyaluronidases. One patient with Type 12 pneumococcal toxic endocarditis and no evidence of pneumonia exhibited a rise of serum antihyaluronidase titer from the titer of 1:3 to the titer of 1:192 as titrated with Type 2 pneumococcus hyaluronidase.

DISCUSSION

The rises of serum antihyaluronidase titer reported here indicate that hyaluronidase is elaborated in the bacteremic pneumococcal pneumonias. In general following an optimal injection of an antigen there is a lag of a few days before the appearance in the blood of the corresponding antibody. The titer of this antibody rises rapidly to a maximum which usually is attained between the tenth and twenty second day after inoculation²⁸. According to these principles elaboration of hyaluronidase in fourteen of sixteen cases of bacteremic pneumococcal pneumonia began during or before the first week of hospitalization.

The relation of this elaboration of hyaluronidase to the severity of pneumococcal pneumonia is not clear. The rises of serum antihyaluronidase titer which were exhibited by all patients with purulent complication suggest that hyaluronidase may promote increased permeability of pleural meningeal, or synovial tissues. In corroboration of this impression all patients whose serum exhibited no increase of antihyaluronidase titer were free of purulent complica-

tion Increase of antihyaluronidase titer could not be correlated with the number of lobes involved by the pneumonia since the average number of lobes involved was similar in all groups

The antihyaluronidase reported here may be similar to the nonantibacterial therapeutic factor which was reported to be present in antipneumococcal horse serum by Sabin in 1932²⁷

The occurrence of small amounts of antihyaluronidase antagonistic to pneumococcus hyaluronidase in the serum of all of fifty normal human beings is notable, but its significance is obscure Ten of these people were high school youths 17 and 18 years of age, and forty were medical personnel of the Cincinnati General Hospital between 20 and 30 years of age

The absence of type specificity of the antihyaluronidase response in pneumococcal pneumonia is consistent with the finding of Fliou and Wenner²⁸ that an inhibitory substance in the serum of rabbits immunized with pneumococcal neutralized enzymes (hyaluronidases) derived from six different types of pneumococci

SUMMARY

Antihyaluronidase in the serum of fifty normal human beings antagonistic to Type 2 pneumococcus hyaluronidase was compared with the same antihyaluronidase in the serum of Patient A. T. who was six months convalescent from Type 2 pneumococcus endocarditis All of the fifty normal subjects tested had some degree of this antihyaluronidase Since subsequent experiments demonstrated that serum antihyaluronidase antagonistic to pneumococcus hyaluronidase is not type specific, these observations upon the sera of normal human beings pertain to hyaluronidase elaborated by all types of pneumococci

Serum sera of twenty six patients with primary pneumococcal pneumonia were tested for antihyaluronidase by titration against hyaluronidases in culture filtrates of Type 1, Type 2, and Type 7 pneumococci Seven patients with negative blood culture and no purulent complication exhibited no change of antihyaluronidase titer Eight of eleven patients with pneumococcus bacteremia and no purulent complication exhibited rises of antihyaluronidase titer which were fourfold or greater All of eight patients with pneumococcus bacteremia and purulent complication exhibited rises of titer of fourfold or greater The rises of antihyaluronidase titer which were observed were not specific for pneumococcus type

Therapeutic antipneumococcal rabbit serum exhibited less antagonism to pneumococcus hyaluronidase than did a majority of the sera from fifty normal human beings High therapeutic concentrations of penicillin and sodium sulfadiazine exhibited no antagonism of pneumococcus hyaluronidase

A rise of serum antihyaluronidase titer could not be brought about in one patient with pneumococcal pneumonia by the intravenous administration of therapeutic antipneumococcal serum, but a progressive rise of serum agglutinating titer for the homologous pneumococcus was produced

CONCLUSION

Rises in the titer of serum antihyaluronidase antagonistic to pneumococcus hyaluronidase, found in sixteen patients with bacteremic pneumococcal pneumonia, indicate that hyaluronidase was elaborated and was antigenic in these pneumococcus infections. This elaboration of hyaluronidase was apparent during the first week of hospitalization in fourteen of these sixteen patients with pneumonia. The elaboration of hyaluronidase appears to be related in some way to the development of purulent complications in pneumococcal pneumonia.

THE ROLL OF HIGH BLOOD PENICILLIN LEVELS ACHIEVED WITH CARONAMID IN PENETRATING THE BLOOD BRAIN BARRIER

HENRY D. JANOWITZ, M.D., S. STANLEY SCHNEIFERSON, M.D., MARCY L. SUSSMAN, M.D., AND FREDERICK H. KING, M.D.
NEW YORK, N. Y.

IN A previous report¹ we described a method for producing sustained high penicillin levels in the blood. This consisted of frequent rapid intravenous injections of large doses of crystalline penicillin in conjunction with the oral administration of Caronamide (4-carboxyphenylmethanesulfonamide). The latter inhibits tubular excretion of the antibiotic. The method was found to be safe and effective.

In a review of previous investigations Wyle² reported disagreement on the question of whether any penicillin traverses the blood brain barrier under normal and abnormal conditions. When penetration into the spinal fluid was reported the levels recorded were low. Smith and collaborators³ gave 100,000 units of penicillin intravenously to patients with normal and inflamed meninges and found only traces of penicillin in the spinal fluid. They concluded that the meninges are relatively impermeable to penicillin. Schwemlein and co-workers⁴ administered penicillin by intravenous drip in amounts varying from 10 to 20 million units in twenty-four hours and found the highest spinal fluid level thus achieved to be 0.55 Oxford unit per milliliter. Because of these and similar findings by other authors, cerebrospinal infections have been treated by the intrathecal route a procedure not without hazard.^{5,6}

For the study reported below twelve patients free of infection of the central nervous system were selected. In eight of these twelve patients one million units of crystalline penicillin were administered rapidly intravenously every hour for ten hours. In four, namely Patients 3, 4, 5, and 7 a continuous intravenous infusion of 10 per cent glucose in 1,000 cc. of distilled water was administered during the ten-hour period and the penicillin was injected every hour into the distal end of the rubber tubing. Eight patients received Caronamide in doses of 4 Gm. every three hours starting eighteen hours prior to and continuing during the period of administration of the antibiotic. These included six patients who received the hourly injections and two who received penicillin along with a continuous intravenous injection of glucose. For comparison Caronamide was withheld from the remaining four patients.

The peripheral venous blood and the spinal fluid samples were obtained approximately fifteen minutes after the last (tenth) injection of the penicillin. In some of the patients specimens also were obtained fifteen minutes after the fifth as well as the tenth injection and fourteen hours after the last (tenth) injection.

From the First Medical Service and the Division of Bacteriology Laboratories of the Mount Sinai Hospital.

Received for publication May 6, 1948.

The method of penicillin assay was a broth tube dilution method using *Staphylococcus aureus*, strain H, as the standard organism and flesh meat extract broth as the medium. The minimal concentration of the standard penicillin* required to inhibit the inoculum of 5×10^2 *Staph aureus* strain H cells was 0.02 unit per milliliter. All titrations of blood and spinal fluid levels were accompanied by and compared with this standard.

9			20.0	0.133		

*Injection made into tubing of continuous intravenous drip

It may be seen from Table I that substantial penicillin levels were achieved in the cerebrospinal fluid, especially when Caronamide was employed as an adjuvant. The levels in this group ranged from 1.0 to 6.6 units per milliliter of spinal fluid with an average of 4.0 units per milliliter. In two patients tested after the fifth injection a level of 2.0 units of penicillin per milliliter of spinal fluid was present. Penicillin was still found in the spinal fluid in the patients tested fourteen hours after the last injection.

In a number of instances the blood penicillin levels were not as elevated as had been anticipated. This occurred in two patients who received the antibiotic via the intravenous tubing through which a 10 per cent solution of glucose was being administered. It is believed that such factors as dilution and loss of penicillin because of diuresis may have played a role. In all the patients who received intermittent injections and Caronamide, the blood penicillin levels were markedly elevated as previously reported.¹ Considerably less penicillin was found in the blood and spinal fluid of those patients who did not receive Caronamide.

These studies demonstrate that substantial penicillin levels can be attained in the cerebrospinal fluid of patients with normal cerebrospinal systems. These levels are presumably due to the elevated blood levels and not to a change in permeability of the meninges. However, it is possible that even higher levels

*Obtained from the United States Department of Agriculture

might be attained in the presence of diseased and more permeable membranes. In such cases intrathecal administration of penicillin in the treatment of the infections might prove unnecessary.

SUMMARY

High penicillin levels in the cerebrospinal fluid were produced in normal individuals by a method designed to produce high sustained blood levels. In three instances the presence of the antibiotic was still demonstrable in the spinal fluid fourteen hours after the last intravenous injection of penicillin.

THE EFFECT OF SODIUM SALICYLATE UPON SERUM DISEASE IN RABBITS

KATHARINE SMULL,* M D, ROBERT W. WISSLER, PH D,
AND JAMES M. WATSON, B S
CHICAGO, ILL

INTRODUCTION

THE therapeutic value of salicylates in the treatment of acute rheumatic fever and serum sickness has long been recognized,^{1 2} but most clinical experience has indicated that these drugs have no specific effect upon the disease processes.^{3 4 5} There has been little opportunity however to observe whether the lesions of these diseases are altered by salicylate therapy. Although an experimental approach would be helpful in evaluating the histopathologic effects of these drugs, in the past this type of study has been impossible because of the absence of a suitable counterpart of rheumatic fever or serum sickness in animals. Recently such an opportunity has been offered by the production of serum disease in rabbits⁶ and the demonstration that it is characterized by lesions of the arteries and heart which are similar in several respects to those of acute rheumatic fever.⁷

The following experiments were undertaken, therefore, to test the influence of sodium salicylate therapy upon the lesions resulting from the injection of rabbits with large intravenous doses of normal horse serum. Because a previous study had suggested that the necrotizing arteritis which some rabbits develop following horse serum injection might be due in part to arterial spasm,⁸ the opportunity was taken to study the arterial blood pressures of some of the animals during the course of development of the lesions. In addition the erythrocyte sedimentation rates of the rabbits were measured, since preliminary observations indicated that they became elevated during the course of serum disease in the rabbit as in man. It was hoped that these determinations might give a clinical measure of the severity of the developing lesion where other criteria had failed. We also wished to ascertain the effects, if any, of salicylate therapy upon the increased sedimentation rates.

EXPERIMENTAL PROCEDURE AND MATERIALS

Two experiments were performed. In the first, fifteen rabbits were used. During a preliminary period of eight days before the first injection of horse serum, four determinations of each animal's blood pressure and sedimentation rate were made to establish normal values. On the first day of the experiment all but two of the rabbits were injected with 10 ml. kilogram of horse serum intravenously. The two uninjected animals served as controls for the blood pressure determinations and the other for salicylate therapy. Arterial blood pressures and erythrocyte sedimentation rates, the latter always accompanied by cell counts

Received for publication May 24 1948

*La Rabida research fellow for 1947-1948

determinations, were measured on alternate days throughout the experiment. On the sixth day following the initial injection of horse serum a number of the rabbits began to show elevated sedimentation rates and erythematous ears⁶ suggesting a developing serum reaction. Sodium salicylate treatment was then begun in half the injected rabbits and one of the un.injected controls. In the treatment of acute rheumatic fever Coburn advocated maintaining plasma salicylate levels above 350 gamma per milliliter. Because this average level in rabbits almost always results in severe toxicity, the drug was administered in quantities designed to maintain an average of about 250 gamma per milliliter throughout the twenty-four hour period. The animals were paired so that those showing similar sedimentation rate increases were divided between the salicylate-treated and the untreated groups. Salicylate therapy was continued through the tenth day when it was assumed that the tissue reaction to the first injection of horse serum was complete.⁶ On the sixteenth day of the experiment salicylate therapy was resumed in the treated rabbit. Since in our experience arteritis has been produced in greater intensity and in more animals following a second large injection of horse serum, all of the animals were reinjected intravenously on the seventeenth day of the experiment with 10 ml per kilogram. Salicylate therapy was continued for the following eleven days at the end of which time the treated rabbits and their controls were sacrificed and autopsies were taken for histologic study.

Twenty-two rabbits were used in the second experiment which was similar in plan to the first with the following exceptions. Blood pressures were not determined. Sedimentation rates and hematocrits were each measured twice before the experiment started: five, seven, nine, twelve, and fourteen days after the first injection of horse serum and two, four and six days after the second injection. Eighteen rabbits were injected with horse serum; three received salicylate only and one served as a control on the effects of bleeding. Ten rabbits of the group injected with horse serum were treated with salicylate beginning on the sixth day and treatment was continued in the survivors until the experiment ended. A second injection of horse serum was given on the sixteenth day of the experiment and the survivors were sacrificed on the twenty-second day.

Animals.—Thirty-seven adult rabbits of both sexes were used. With the exception of four animals they were all Illinois. Their initial weights varied from 1.9 to 3.9 kilograms. They were caged singly and fed a commercial rabbit food and water ad libitum.

Horse Serum.—Two lots of normal horse serum without preservatives were used, one for each experiment. An aliquot of each was cultured immediately before it was injected and was found to be sterile. The serum was injected slowly into a lateral ear vein using sterile precautions.

Sedimentation Rates.—These were determined using thick-walled capillary tubes with the specifications of Westergren.¹ The tubes were filled to a 20 cm mark and their lower ends were plugged with modeling clay. They were kept in a vertical position by the method suggested by Foster.¹² Dry oxalate mixture¹³ served as the anticoagulant. Hematocrits were always determined simultaneously by a micromethod.¹ The sedimentation rate readings were made at two hours and were corrected for anemia with data obtained in this laboratory by Tusling,¹⁰ who employed this technique with the same strain of rabbits. With this method the healthy rabbit with a normal hematocrit has a two-hour sedimentation rate of less than 5 millimeters.

Arterial Blood Pressures.—These were measured using the method and apparatus described by Grunt and Rothschild.¹⁷ The same point on the same ear artery was used for each determination. The ear was always warmed until there was maximal vasodilatation in front of the light which served as the source of illumination for the readings. Then three readings were made in rapid succession and the average was recorded as the blood pressure. Both systolic and diastolic readings were obtained.

Sodium Salicylate Administration.—Preliminary experiments indicated that it was necessary to give a total quantity of 750 m. per kilogram in divided doses each day in order to maintain salicylate levels of approximately 250 gamma per milliliter or above throughout most

Rockland Rabbit Culletts

kindly supplied by Dr. E. G. Jones of the Lilly Research Foundation, Indianapolis, Ind.

of the twenty four hour period. In the first experiment the salicylate was administered to each treated rabbit in three divided doses of 250 mg per kilogram at 8:30 A.M., 1:30 P.M., and 10:30 P.M. Two routes of administration were tried in this experiment. On days seven, eight, and nine a 5 per cent solution of sodium salicylate in distilled water was fed by stomach tube. Because of technical difficulty in passing the tube and the death of one of the rabbits from tracheal passage, the drug was given subcutaneously in a 4 per cent solution on the tenth day. When therapy was resumed on the sixteenth day the subcutaneous route was again used and continued until the twenty eighth day. An occasional dose was omitted if the animal appeared toxic.

In the second experiment, a 5 per cent aqueous solution of sodium salicylate was given by stomach tube throughout the treatment period. This route was chosen because further observations had indicated that a more sustained level could be attained in this fashion and further experience had made this route safer. Although the times of administration were similar to those of the first experiment, the amount of drug was varied from rabbit to rabbit and from day to day as follows. A total of 850 mg per kilogram divided into three doses was given for the first twenty four hours. Thereafter the daily quantities were adjusted according to the plasma levels obtained in an attempt to maintain comparable level. The divided doses varied between 75, 75, and 100 mg per kilogram per day and 300, 300, and 300 mg per kilogram per day. The larger amount always was given at 10:30 P.M. in an attempt to maintain a high level over the ten hour period at night.

Plasma Salicylate Determinations.—These were made according to the colorimetric method of Brodie, Udenfriend, and Coburn¹⁸. Readings were taken with a Klett Summer on photoelectric colorimeter using a filter with a wave length of 540 millimicrons. On the days when determinations were made on the treated rabbits, an equivalent amount of blood was drawn from the untreated rabbits in order to equalize blood loss.

Antibody Titers.—Serum was collected on the sixteenth day in the first experiment and on days seven, fourteen, and twenty one in the second experiment from all the rabbits. This was stored in paraffin sealed tubes at -20°C until the end of the experiment when precipitin titers to horse serum were determined by the collodion particle agglutination technique of Cannon and Marshall¹⁹.

Histologic Studies.—The animals which survived were sacrificed by air embolism. In the first experiment a single transverse section through the base of the heart was made, in the second, four sections of the heart were made, one through each of the four valve rings. In addition, in each experiment sections of the lungs, mediastinum, diaphragm, liver, stomach, pancreas and spleen, mesenteric lymph nodes, left kidney, left adrenal, bone marrow, and testis or uterus and ovary from each rabbit were examined. All tissues were fixed in Zenker formalin solution, embedded in paraffin, and stained with hematoxylin and eosin.

EXPERIMENTAL RESULTS

Sedimentation Rates.—Fig. 1 shows the corrected two hour erythrocyte sedimentation rates and the mean rates found in the treated and untreated groups in the second experiment. The changes in the sedimentation rates in the two experiments were so similar that only those of experiment two are given in detail. Normal rates persisted in the salicylate treated and bleeding control animals which did not receive intravenous horse serum. Of the thirty one animals given horse serum only five failed to show a rise above 20 mm after the first or second injection. The rate usually began to rise from the fifth to the seventh day at the time when the first manifestations of hypersensitivity were seen. A further elevation usually occurred one to two days after the second injection of horse serum when presumably the extent and severity of the lesions were increasing. Salicylate treatment did not exert any notable effect on the sedimentation rate in spite of the fact that the lesions were less severe in this group of animals.

No lesions except those attributable to hypersensitivity could be found at autopsy to account for the observed change of the sedimentation rate.

It should be noted that all of the rabbits showed a decreased cell volume. The average hematocrit of twelve salicylate treated animals fell from 42.0 to 25.8 per cent, while the average of twelve untreated rabbits fell from 41.0 to 30.7 per cent. Similarly, the hematocrits of the rabbits receiving salicylate alone dropped about twice as much as those of the bleeding controls. It appears that salicylate in this dosage increases the anemia which rabbits receiving large doses of horse serum develop.

Fig 1—Erythrocyte sedimentation rates of rabbits injected with horse serum

Blood Pressure Findings—For purposes of comparison the nine rabbits which received two injections of horse serum and survived to the end of the first experiment were divided into three groups (Fig 2). Group A consisted of three rabbits which at death manifested severe arteritis. Group B was composed of three similarly injected rabbits which developed minimal or no arteritis and Group C the three rabbits which received both serum and salicylate and which also showed only slight arterial reaction. Only the systolic pressures are recorded in the graph since the changes in the diastolic pressures were parallel.

Sustained hypertension was not noted in any animal of these three groups. It is of interest however that there was a definite trend for the arterial pressures of the untreated groups (A and B) to rise following the first injection of horse serum. However this was no more marked in the rabbits which later exhibited lesions than in those which reacted with little or no arteritis. This elevation was most evident from day seven to day eleven following injection an interval con-

responding to the manifestations of serum disease in the rabbit, namely erythema,⁶ temperature rise,²⁰ and rise in sedimentation rate (Fig 1). On the other hand the treated rabbits which were receiving salicylate during this period (day seven through day ten) showed a sharp drop in blood pressure. When salicylate therapy was stopped there was a rise toward the preinjection level.

Fig. 2—Mean systolic blood pressures of rabbits injected with horse serum.

The second injection of horse serum on the seventeenth day was accompanied by a fall in the arterial blood pressure which was most apparent in the two untreated groups, A and B. The remainder of the observation period was characterized by a gradual rise of the arterial pressure in Groups B and C to values comparable to the preinjection levels (Group C) or slightly higher (Group B). The rabbits which were developing marked generalized arteritis (Group A) showed no significant change in their blood pressure from day nineteen to day twenty-seven. Furthermore the drop in blood pressure observed in the salicylate treated group in the first treatment period did not recur during this course of therapy.

Salicylate Levels—Maintenance of adequate salicylate levels was difficult because of wide variation in the animals' tolerance for the drug. In spite of careful adjustment of individual doses, seven rabbits died of salicylate intoxication before the completion of the experiments. The level was considered to be adequate during most of the twenty-four hour period if a plasma concentration of 150 gamma per milliliter or more was present five hours after the previous administration of the drug. In the first experiment plasma salicylate levels were

determined on days ten and eighteen at six hours and on the twentieth day at three hours after the morning dose. These levels were always above 150 gamma and the average of the three determinations in each animal ranged between 343 and 544 gamma. In the second experiment plasma salicylate concentrations were measured on the eighth day twelve hours after the evening dose of drug and on days nine, twelve, fourteen, sixteen and nineteen five hours after the morning dose. Individual values ranged between 0 and 530 gamma. In four animals, average five hour levels were between 254 and 353 gamma. The other four animals had average five hour readings of 90 to 128 gamma but were receiving such large amounts of salicylate (0.9 to 1.1 Gm. per kilogram per day) that it did not seem wise to increase the dose further.

Histopathologic Findings—Table I summarizes the findings in experiment one in four treated and four untreated rabbits which were paired on the basis of similar responses in sedimentation rate following the first injection of horse

serum. One pair died of an anaphylactic shock immediately following the second injection of horse serum and the other three pairs survived to the end of the experiment. The lesions were graded separately by two observers from 1 plus to 4 plus depending upon their extent and severity. The extent of the valvular lesions could not be evaluated in this experiment because of the manner in which the heart sections were made. It should be noted that the numbers of animals to be compared were small in this experiment because two salicylate treated rabbits died on days eight and nine. Despite the small series the results strongly suggest that salicylate treatment had depressed the developing arteritis in the salicylate treated group.

Fig 4—Mitral valves of rabbit treated with sodium allylate (Rabbits 4, 41, 42 and 43) compared with their untreated controls (Rabbits 15, 17, 40 and 43). Magnification 100x.

Table II summarizes for experiment two the histologic findings in eight treated rabbits paired with eight untreated rabbits on the basis of the rise in the sedimentation rate after the first injection of horse serum. Two salicylate treated rabbits which had been injected with horse serum died early, one of false passage of the stomach tube and one of salicylate intoxication. These were eliminated from the experiment. Five salicylate treated animals died later, one of false passage of the stomach tube and four of salicylate intoxication. One died on day fourteen, two on day eighteen, and two on day nineteen. In each instance the paired untreated control animal was sacrificed on the same day.

It may be seen from Tables I and II that the lesions of the salicylate treated rabbits were considerably less severe and extensive than those observed in the untreated group. This fact is further emphasized by Figs 3 and 4 which illustrate the changes in the mitral valves in each pair of rabbits in experiment two. For reasons which are not clear there was a much greater degree of necrotizing arteritis in the animals of experiment one, while the lesions observed in the second experiment were more severe in the myocardium and heart valves.

Fig. 5—Area of necrosis in the right ventricle of Rabbit 60. Magnification $\times 140$.

Microscopically the arteritis, when present, usually was seen in the medium sized arteries of the myocardium, lungs, pancreas, mesentery, stomach, kidney, liver, adrenal, diaphragm, and testis or uterus. Valvular changes, mostly proliferative in type, were found predominantly at the base of the valve leaflets. The latter were confined almost entirely to the mitral and aortic valves as they are in rheumatic fever. These lesions were all similar qualitatively to those described by Rich and Gregory.⁷⁻⁹

An additional lesion was noted in the myocardium, to our knowledge, that has not been reported previously in rabbits with serum disease. The lesion con-

sisted of many areas of necrosis of varying size occurring almost exclusively in the myocardium of the right ventricle (Fig 5). In no instance did we observe thrombosed arteries in the hearts which showed these lesions. Although the myocardial fibers in the areas were disrupted and undergoing necrosis there was a notable absence of infiltration by inflammatory cells. In the older lesions there was early organization so that the whole area was composed of a network of large mononuclear cells. These appeared to be somewhat abnormal large macrophages or young fibroblasts with clear chromatin poor nuclei and large deeply staining nucleoli (Fig 6). The lesions were not seen in the animals which did not receive horse serum.

Fig 6—Higher magnification of an area at the edge of the lesion in Fig 5. Magnification $\times 900$

The renal lesions usually were localized to the point where afferent arterioles entered glomeruli. At that point there was an apparent proliferation of endothelial cells or cells of the juxtaglomerular apparatus accompanied by a variable infiltration of lymphocytes. No significant changes were seen in the glomerular tufts. These lesions were mild and were observed in only a few animals (Tables I and II).

Except for pulmonary hemorrhage and edema and glycogen depletion of some of the livers there were no changes in the tissues of the salicylate treated animals or the salicylate controls which could be attributed to toxic effects of the drug.

Antibody Titers—Titers of sera obtained from the rabbits sixteen days after horse serum injection in experiment one and seven and fourteen days after injection in experiment two were similar in the treated and untreated groups. Appreciable differences in precipitin titers between the salicylate treated and untreated rabbits occurred in sera drawn eighteen to twenty two

days after the first injection of horse serum in the second experiment (two to six days after the second injection) These are recorded in Table II where it can be seen that with one exception higher titers were recorded for the untreated member of each pair The only pair of rabbits in which this difference was not observed (Rabbits 57 and 43) showed the least contrast in the severity and extent of their lesions

DISCUSSION

The blood pressure observations do not support the concept that the arterial lesions develop as a result of arterial spasm¹⁹ or that hypertension is the important common factor in the pathogenesis of experimental periarteritis.²¹ This is in agreement with the experimental results of Hopps and McCollum²² who failed to find a correlation between blood pressure changes and the lesions occurring in rabbits receiving large doses of horse serum The transient elevation of blood pressure following the initial injection of horse serum might be interpreted as a manifestation of a generalized arterial constriction Its inconstant occurrence following the second injection of serum and the lack of correlation of the rise with the development of arterial lesions make it untenable to assign to hypertension any significant role in the developing arteritis On the other hand, the observations do not disprove the hypothesis that local arterial spasm may occur and be of some importance in the development of the arterial lesions It is possible that the medial ear arteries utilized for the blood pressure determinations were unsuitable to reflect a generalized vasospastic reaction For the present the question of this phase of the pathogenesis of these arterial lesions must be left unanswered

The erythrocyte sedimentation rate appears to offer a clinical measure of the developing lesions of hypersensitivity although the extent and severity of the lesions found do not always correlate with the degree of rise in sedimentation rate Contrary to the clinical findings of some observers,^{23, 24} sodium salicylate exerted little if any suppressive effect on the erythrocyte sedimentation response

In these experiments an attempt was made to give the rabbits massive doses of salicylate comparable to those advocated by Coburn for human beings.¹¹ However, as had been noted previously in patients given large doses of salicylates the quantities necessary to maintain a high salicylate blood level vary widely It is extremely difficult to maintain a sufficiently high level in the rabbit without producing severe toxic reactions which often terminate in death It appears from the results that the salicylate blood levels were adequate in most instances although levels of 150 gamma or less were noted at some period of the twenty-four hours in many of the animals

It is obvious that the severe toxic reactions which some of the rabbits exhibited as well as the anemias which most of them developed may have acted in a nonspecific fashion to prevent the development of the lesions It should be noted however that the contrast between the lesions of the treated and untreated rabbits was not limited to those which showed toxic symptoms Furthermore when an animal died with salicylate intoxication it usually had been noticeably sick for only a few hours, whereas the lesions appeared considerably older

will be important nevertheless to ascertain whether the lesions of rabbit serum disease can be prevented or treated with doses of salicylate which do not produce toxicity.

At present one can only speculate as to how salicylates produce their effects. It has been reported that salicylates depress antibody formation.²⁶⁻²⁸ Other writers do not agree.³⁰⁻³¹ Our studies suggest that antibody formation was somewhat diminished in the salicylate treated group late in the experiment. However since the concentration of antibody seems to have little correlation with development of the lesions,¹ the significance of this finding is questionable. Recent work by Dorfman and co-workers³² confirms that of Ueffer³¹ and suggests that sodium salicylate inhibits the spreading effect of hyaluronidase.

The question of whether salicylates merely suppress the symptoms or whether they exert a specific influence upon the lesions of rheumatic fever has been reopened recently by Coburn.³³ He has emphasized the possible specific action of large doses of salicylates in suppressing the rheumatic process and preventing the ensuing carditis. A few confirmatory studies have emphasized the need to administer the massive quantities of salicylate early in the course of the disease.³²⁻³⁴ However, Keith and Ross⁴ found that even early treatment with large doses of salicylate did not hasten restoration of the sedimentation rate or diminish the incidence of subsequent heart damage as compared with early treatment with small doses of the drug. Others have reported that the intensive salicylate therapy recommended by Coburn did not alter the inflammatory reaction of rheumatic fever in the joints³ or heart⁵ in patients of whom most had had rheumatic fever for four or more weeks before treatment. Similarly, Wegria and Smull³⁵ found the duration of rheumatic attacks to be unaffected by massive doses of salicylate but suggested that early treatment might have proved efficacious. At present, then, the clinical value of maintaining high salicylate levels in the treatment of acute rheumatic fever is still on trial. It appears however that if salicylates are to produce a specific effect upon the lesions of rheumatic fever they must be given early in the course of the disease.

In contrast to the findings of Thomas and Sturmfeld³ our results show that sodium salicylate, given in large doses early in the course of serum disease in rabbits reduces the extent and severity of the resulting lesions. It must be emphasized that in these experiments salicylate therapy was begun six days after the initial injection of horse serum at a time when the lesions of hypersensitivity are presumably just beginning to develop.³⁶ It was continued throughout the period following the second injection of horse serum when it is assumed that the most marked tissue reactions occur. Because of its insidious onset the first attack of rheumatic fever is usually seen by the clinician at a comparatively early stage. However Schlesinger³⁷ and Coburn and Moore³⁸ have reported success in suppressing the rheumatic process by prophylactic administration of salicylate following streptococcal infection in subjects with previous rheumatic episodes. Further experiments are indicated to determine how long following the injection of rabbits with horse serum the salicylate therapy can be initiated and still exert its suppressive effect upon the development of the lesions.

Many have called attention to the clinical and pathologic similarities between acute rheumatic fever and serum sickness,³⁹ and in our opinion rabbit serum disease represents the closest approximation to acute rheumatic fever yet produced experimentally. Despite these attractive similarities, our experience indicates that rabbit serum disease does not fulfill all of the rigid pathologic criteria listed by Gross and co-workers⁴⁰ for the experimental production of rheumatic fever. The Aschoff-like lesions are not numerous. Although their cellular components and location are typical they seldom show fibrinoid necrosis. Pericarditis is very rare and when present it is usually focal and minimal. Vegetae are uncommon in the valvular lesions and we have been unable to produce chronic valvular lesions like those in rheumatic fever by many repeated injections of horse serum over long periods of time.⁴¹ Therefore at present one must be cautious in assuming that the inhibitory effect of salicylates upon the lesions of rabbit serum disease can be applied to the lesions of rheumatic fever.

SUMMARY AND CONCLUSIONS

The histopathologic lesions produced in twelve rabbits receiving two intravenous injections of sterile normal horse serum fifteen to sixteen days apart in doses of 10 ml per kilogram have been compared with those produced in twelve similarly treated rabbits which also received large doses of sodium salicylate starting six days after the first injection of horse serum. Blood pressures were determined repeatedly in some of the rabbits (experiment one). Sedimentation rates and blood salicylate levels also were followed.

It is concluded that

The arterial blood pressure of rabbits receiving large doses of horse serum showed no sustained elevation, and no evidence was obtained that a generalized arterial constriction plays a part in the pathogenesis of the arteritis of rabbit serum sickness.

The erythrocyte sedimentation rates of rabbits given large intravenous injections of horse serum appear to offer a clinical measure of the developing lesions of hypersensitivity. Although the degree of rise could be correlated to some extent with the severity of the lesions found, this correlation was not constant.

It is difficult to maintain salicylate levels of 350 gamma per milliliter recommended for man without producing intoxication and death in rabbits.

A moderate depression in the concentration of circulating antibody to horse serum was noted in the salicylate treated rabbits of the second experiment as compared with the untreated controls. This occurred eighteen to twenty-two days after the first injection of horse serum. Antibody concentrations earlier in the experiments were not significantly different in the treated and untreated groups.

A lesion of the right myocardium which occurred more frequently in the untreated rabbits is described. This consisted of focal necrosis accompanied by little inflammation.

The lesions seen in the salicylate treated rabbits, especially the arterial and valvular lesions, were greatly reduced in severity and extent as compared with those in the untreated animals

ALTERATIONS OF RADIAL OR BRACHIAL INTRA-ARTERIAL BLOOD PRESSURE AND OF THE ELECTROCARDIOGRAM INDUCED BY TILTING

ROBERT S. CREEN, M.D. ARNOLD HLAUER, M.D. AND JOHNSON MCGUIRE, M.D.
CINCINNATI, OHIO

INTEREST in the response of blood pressure and pulse rate to postural change was stimulated by the problem of rapid evaluation of tachycardia in military induction examinations. Preliminary observations indicated that a significant slowing of heart rate occurred with tilting to a head down position in subjects with tachycardia secondary to excitement. On the other hand this slowing did not occur in inductees with tachycardia which was later found to be due to organic disease. An increase of blood pressure occurred in all subjects during the tilt to the head down position. In this study careful analysis has been made of the response of heart rate and blood pressure to tilting in normal subjects in order to establish a standard to evaluate changed reactions due to disease or drugs.

Hill¹ first demonstrated the importance of gravity in the circulatory system of man. He also reported that the brachial systolic blood pressure as measured by the sphygmomanometer remained approximately the same on tilting from an erect to a head down position providing the readings were taken with the arm in the frontal plane perpendicular to the long axis of the body (horizontal plane). With the arm in this position the effect of gravity on the column of blood within the arteries of the arm remained constant.² These readings were not taken during or immediately following postural change but after the subject was in the altered position for an appreciable period of time. Wald, Cuenney and Scott⁴ using a Tycho's self recording sphygmomanometer found that following a positional change from horizontal to standing the brachial blood pressure fell below the level obtained in the recumbent position in about ten seconds and then remained or exceeded this level within thirty seconds. Their results with tilting from standing to horizontal position varied in the two subjects studied. Other attempts to analyze the brachial arterial blood pressure changes with tilting have resulted in widely divergent findings.³ There are two important explanations for the discrepancies in these reports. (1) It is impossible to obtain accurate readings of a rapidly changing blood pressure with a cuff method and (2) the position in which the arm was maintained during the tilting has varied in the different experiments.

Slowing of the heart rate following a change from an erect to a horizontal or head down position has been described by numerous observers.^{5, 10, 11} However these findings were interpreted from periodic pulse rate readings and the slowing was not consistently found in all normal subjects.

From the Cardiac Laboratory Cincinnati General Hospital College of Medicine University of Cincinnati
This study was carried out under a grant from the Life Insurance Medical Research Fund

Received for publication March 29 1948

In these studies we have recorded intra arterial blood pressure continuously with the arm maintained in a horizontal plane. Heart rate and rhythm have been interpreted from an electrocardiogram taken throughout the experiment.

METHOD

Direct measurements of radial or brachial artery pressure during and after tilt have been obtained in more than two hundred subjects. This report details the findings of fifteen healthy young adults considered to have normal cardiovascular systems. Simultaneous electrocardiograms were obtained in these subjects, and in addition continuous electrocardiograms have been recorded in one hundred normal adults during and following tilting.

Fig 1—Tilt table for study of cardiovascular dynamics. A, B, C Fulcrum at horizontal region. A, horizontal. B, 45 degree head-down position. C, 20 degree erect position. D, Fulcrum at iliac crest region.

The subjects were tilted at a moderate rate from the 20 degree head up position to the 15 degree head down position. This position was maintained for at least fifteen seconds. The subjects then were returned to the original position.

Tilting was controlled by means of an electrically operated table (Fig 1). The subjects were securely supported so that muscular activity was not required to maintain the position.

The blood pressure tracings were determined by means of a Statham strain gauge adapted in our laboratory to record blood pressure changes by means of a string galvanometer electrocardiograph.¹² The gauge was ideally suited to this type of experiment. It was

*Research Model Cambridge Electrocardiograph Cambridge Instrument Co. Inc. New York, N. Y.

compact (1/2 by 1 by 1 inch) and could easily be held in place during movements. It did not respond to external vibration. Changes of pressure caused an alteration of electrical output that was transmitted to the recording string galvanometer. This output was directly proportional to the pressure; thus linear records were produced.

Preliminary investigation indicated that this system had adequate frequency for accurate pressure recording.

In these experiments a size 20 1 1/2-inch needle with a 45 degree sharp bevel was attached directly to the gauge. The system was completely filled with a solution of heparin (5 mg per cubic centimeter) and the needle with bevel directed toward the heart was inserted into the brachial artery at the elbow or into the radial artery at the wrist.

At least three sets of observations were made on each subject.

RESULTS

Blood Pressure —

Head Down Tilt (20 Degrees Erect to 15 Degrees Head Down) An elevation of arterial blood pressure in the arm occurred during the head down tilt in all of the subjects studied. In general the degree of rise was uniform throughout the tilt; the maximum blood pressure occurred immediately after cessation of motion.

In the subjects with normal cardiovascular systems this elevation of blood pressure (average rise 19 mm Hg systolic/16 mm Hg diastolic) was followed by a gradual fall lasting from eight to eighteen seconds until the blood pressure reached a level that was usually slightly higher than that obtained in the erect position. The average fall in the normal subjects during this period was 13 mm Hg systolic/14 mm Hg diastolic (Figs. 2 and 3).

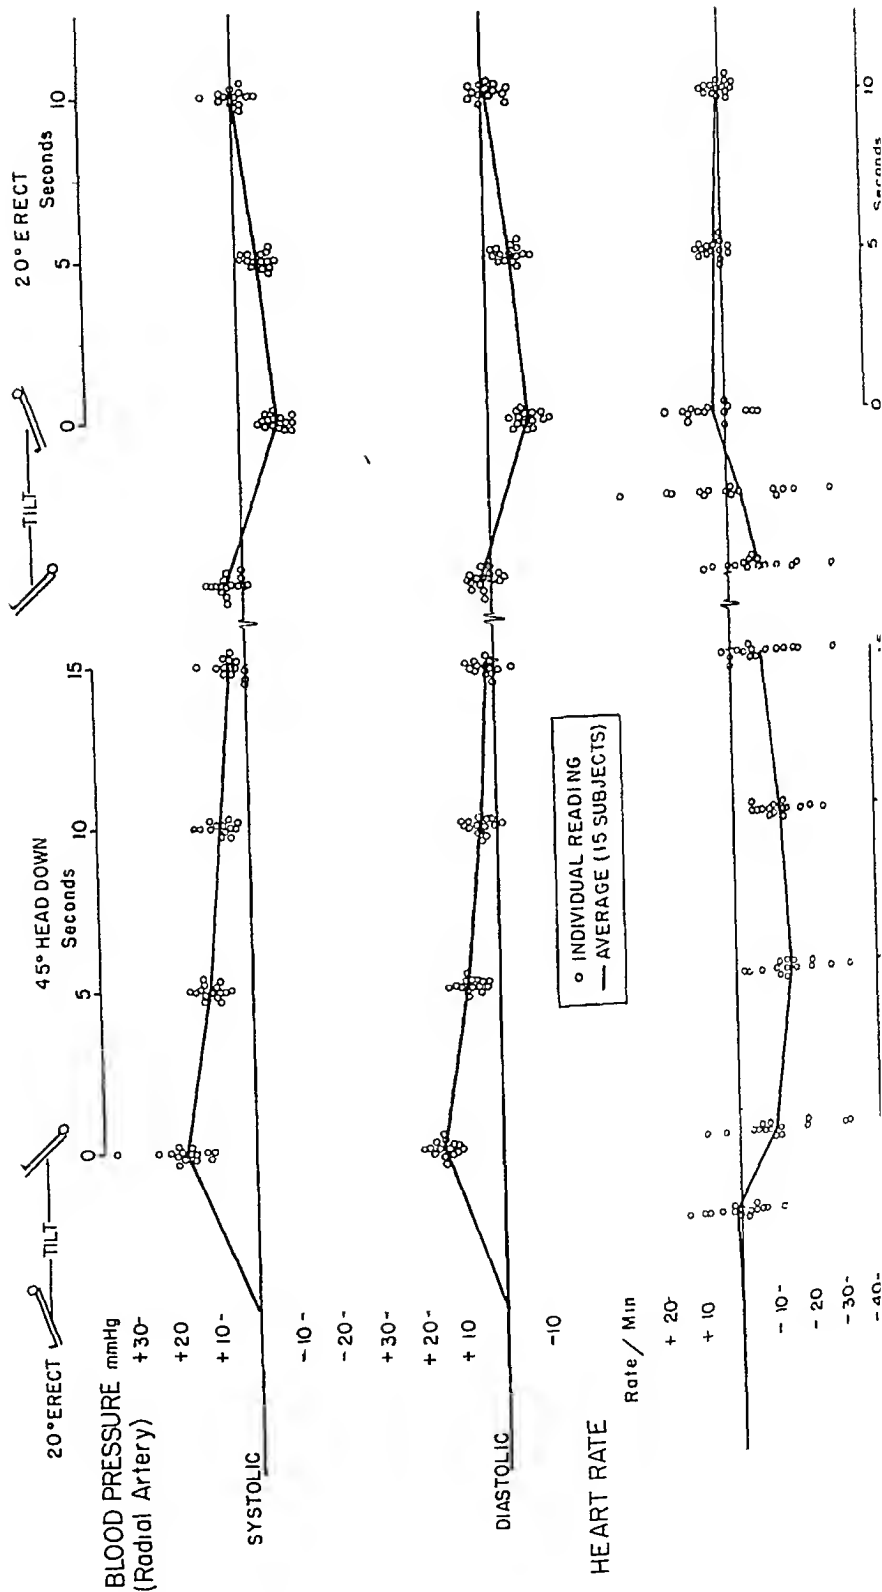

Head Up Tilt (15 Degrees Head Down to 20 Degrees Erect) During the return tilt the blood pressure fell in all of the subjects. This decline was usually uniform throughout the tilt; the lowest blood pressure occurred immediately after the cessation of motion.

In the normal subjects this primary fall of blood pressure (average 14 mm Hg systolic/13 mm Hg diastolic) reached a level below that initially obtained in the erect position, and it was followed by a rise; the blood pressure returned to the starting level within eight to eighteen seconds of the completion of the tilt (Figs. 2 and 3).

Heart Rate —

Head-Down Tilt In subjects with normal cardiovascular systems slowing of the heart rate invariably occurred subsequent to the elevation of blood pressure. The rate for the five second period immediately following the onset of slowing was always less than the erect rate and less than 90 per minute (Figs. 2, 3, and 4). In the majority of cases the onset of slowing was abrupt, resulting in bradycardia which was maintained for a few beats; the rate then gradually increased. In others the slowing developed more gradually. Regardless of the type of the initial response the rate became relatively stable within about fifteen seconds of the completion of the tilt at a rate that was usually slower than previously recorded in the erect position.

Head Up Tilt The heart rate suddenly increased following the drop in blood pressure. This resulted in a rate that was more rapid than the initial

Fig. 3.—Initial intra-arterial pressure and heart rate recording (normal subject, F. J., 63-year-old colored man) Normal cardiovascular system. Con-
tinuous radial intra-arterial pressure and electrocardiogram recorded during, and after tilting to the head down position. The vertical white line indicates the
tenth second interval. Blood pressure. During tilting to the head down position, the pressure fell from 143/80 to 115/96. With the patient maintained
in the head down position, the pressure returned to the initial level of 151/88. During the return to the upright position, the pressure fell to 136/88. With the
patient in the upright position, the pressure returned to the initial level of 151/88. In the head down position, the heart rate fell from 110 to 84 per minute. The
initial tenth second interval increased from 1.1 to 1.3 seconds. With the return to the upright position, the heart rate and the tenth second interval returned to the
initial values.

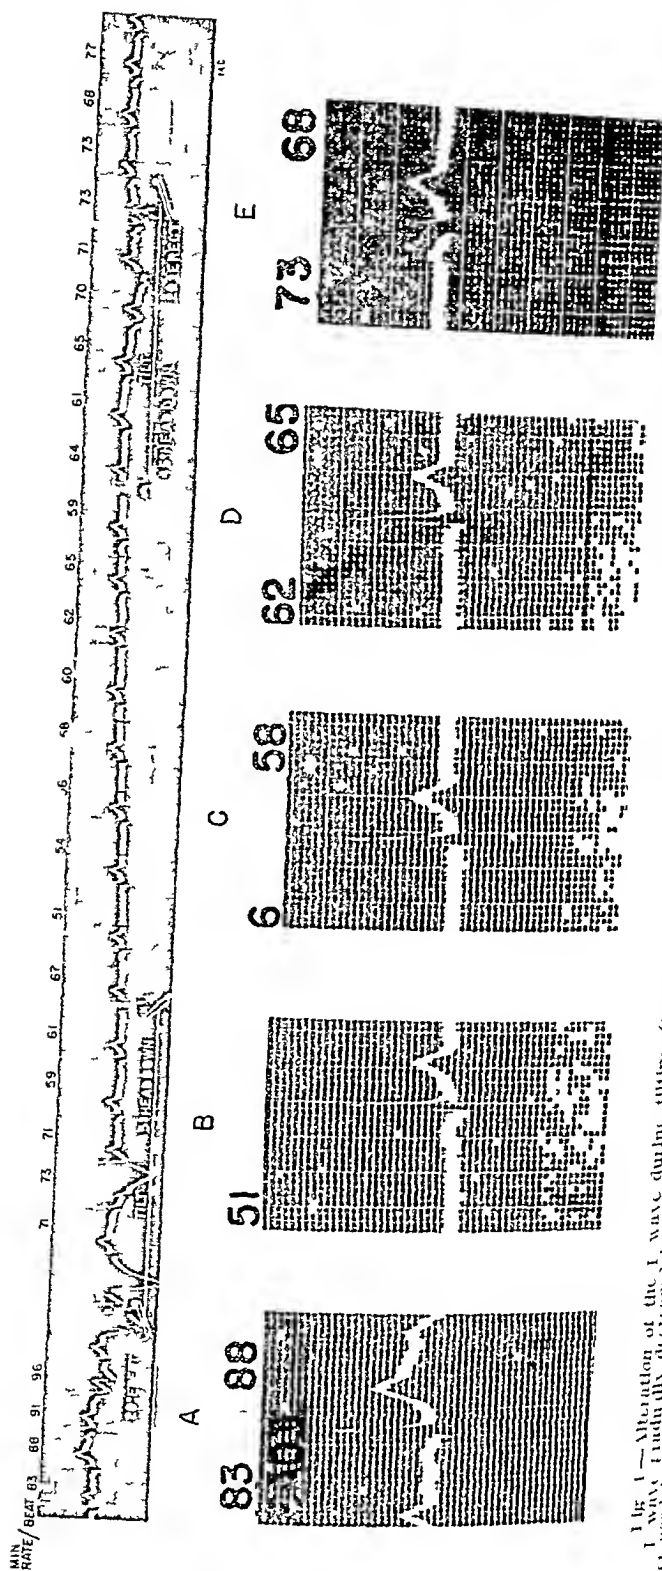

Fig. 1 — Alteration of the I wave during sitting. (normal subject). In the erect position (A) P waves were present. In the head down position the I wave gradually disappeared (B). The I wave interval preceding the disappearance (C) was the same as in the erect position. With the gradual return to the I wave returned to its initial appearance (D).

rate in this position in about half of the subjects. In all instances the rate about ten seconds after the end of the tilt was essentially the same as the original rate (Figs 2, 3, and 4).

Electrocardiogram—Our findings on the effect of positional change on the P-R interval, the QRS complex and the T wave of the normal electrocardiogram are in agreement with those reported by other investigators.^{13, 19} However there are two observations not yet emphasized which we consider worthy of description.

(1) A slowing of the heart rate determined from prolongation of the R-R intervals followed the assumption of the 45 degree head down position in every normal subject.

(2) In twenty per cent of the normal subjects tilted to the head down position the P wave gradually decreased in size and finally disappeared for several beats (Fig. 4). The disappearance of the P wave was not preceded by a shortening of the P-R interval. This change did not invariably occur in the same individual on successive tilting.

DISCUSSION

Blood Pressure—The changes of the radial and brachial intra-arterial blood pressure recorded in these experiments were presumably a reflection of the blood pressure changes in the large arteries that arise from the aortic arch because the arm was maintained throughout the tilt in a position in which the force of gravity of the column of blood within the arteries of the arm remained constant. Our studies have shown that the blood pressure recorded from these arteries invariably rose during the tilt from a head up to a head down position and fell during the reverse tilt. In other experiments we have demonstrated that the blood pressure recorded from the femoral artery always fell during the tilt from the head up to the head down position and rose during the return tilt.² These findings indicated that the primary alterations of pressure that accompanied the postural changes were due to a shift of the hemostatic force of gravity of the column of blood enclosed by the aorta and its branches and were not secondary to reflex changes. These primary alterations of blood pressure apparently acted as intra-arterial stimuli to the regulatory mechanism that controls blood pressure.

In the subjects with normal cardiovascular systems these primary alterations of radial or brachial pressure were followed by a characteristic pattern of depressor response in the head down position and of pressor response in the erect position whereby the blood pressure in the region of the aortic arch returned within eight to eighteen seconds to a level that was approximately the same regardless of the position of the body.

The mechanism of blood pressure regulation has been explored extensively in animals. An elevation of arterial blood pressure stimulates the proprioceptors of the carotid sinus region,¹ the left ventricle, the aortic arch, the thoracic aorta,^{3, 24} and the abdominal aorta. This induces reflex dilatation of the splanchnic and peripheral arterioles¹ and of the large thyroid vascular

bed²⁶ intracranial-extracranial anastomoses,⁻⁷ and slowing of the heart rate,¹ resulting in a return of the blood pressure to its previous level. A fall of arterial pressure induces a diametrically opposite type of vasomotor response.

The presence of both pressor and depressor regulatory responses in human subjects with normal cardiovascular systems has been demonstrated in this study. However, exact analysis of these responses in man awaits further investigation of the sites of initiation, the mechanisms of regulation, and the physical factors that determine the degree of blood pressure rise that occurs during tilting. That man has vascular reflexes which influence blood pressure has been proved through the results of denervation operations and by the fact that stimulation of the carotid sinus area may produce both bradycardia and fall in blood pressure. Evidence that reflexes are important in the postural control of blood pressure is found in the peripheral dilatation³⁰⁻³¹ and the bradycardia that occur on assumption of a head-down position.

The function of the regulatory mechanisms that maintain the pressure in the upper aorta at a relatively stable level can be most clearly thought of as a reaction to protect the brain (and probably the heart) against arterial pressure changes that might harm the individual. At one extreme a marked elevation in intracranial arterial pressure might conceivably result in brain damage and at the other a lowering of cerebral arterial pressure might lead to cerebral anoxia and syncope.

Heart Rate.—In a normal subject an inverse relationship of heart rate to blood pressure has always followed the change of blood pressure produced by tilting. Similar alterations in heart rate have been noted subsequent to the change of blood pressure that occurs during and after the Valsalva experiment and following the occlusion or opening of arteriovenous fistulas.³³

The relation between the position of the body, the blood pressure, and the heart rate in these experiments suggests that the change of rate is one of the reflex mechanisms that regulates blood pressure. In the head down position the initial slowing greatly resembled a braking action. In addition the stabilized rate in this position was characteristically slower than the rate in the erect position even though the blood pressure had returned to the erect level. This indicated that this relative bradycardia was one of the means whereby the potential increase of pressure due to the weight of the column of blood (now directed toward the upper arterial regions) was counteracted.

Although it has been known for many years that slowing of the heart may occur in the head down position, the universal appearance of this reaction in subjects with normal cardiovascular systems has not been appreciated. This is probably due to the fact that the slowing is often of short duration and is detected only through a continuous method of recording.

The disappearance of the P wave for a few beats in a large proportion of normal subjects tilted to the head-down position cannot be explained at present. The fact that the disappearance was preceded by a gradual decrease in amplitude of the P wave and was followed by a gradual increase in amplitude

evidence that position alone was not the responsible factor. The fact that the changes of the P wave were not associated with a shortening of the P R interval indicates that the resultant rhythm was not nodal.

In 1897 Hill³ concluded from his experimental work on the blood pressure and heart rate of animals that the effects of changing the position afford a most delicate test of the vasomotor mechanism. The development of a suitable method of blood pressure recording has made it possible for us to demonstrate that this conclusion is probably valid for human subjects. We feel that this method of study may prove to be of value in obtaining a better understanding of the normal physiology of cardiovascular reflexes and of the influence of disease and drugs on these responses.

SUMMARY AND CONCLUSION

A graphic record of radial or brachial intra-arterial blood pressure during and after tilting at a moderate rate between the 20 degree erect and the 45 degree head down position was obtained in more than two hundred subjects. In this study careful analysis was made of the response of heart rate and blood pressure to tilting in fifteen healthy young adults in order to establish a standard to evaluate changed reactions due to disease or drugs.

Electrocardiograms were recorded in one hundred normal adults during and following tilting.

An immediate elevation of blood pressure occurred in all subjects studied during the tilt from the 20 degree erect to the 45 degree head down position. An immediate fall occurred during the return tilt from the 45 degree head down to the 20 degree erect position.

In the normal subjects these primary alterations of blood pressure were followed by a characteristic pattern of depressor response in the head down position and of pressor response in the erect position whereby the blood pressure returned in from eight to eighteen seconds to a level that was approximately the same regardless of the position of the body.

The heart rate invariably slowed in the head down position and increased in the erect position.

In twenty per cent of the normal subjects tilted to and maintained in a head down position the P wave gradually decreased in size and finally disappeared for several beats. The disappearance of the P wave was not associated with a change of the P R interval. This change did not invariably occur in the same individual on successive tiltings.

DICUMAROL IN EXPERIMENTAL MYOCARDIAL INFARCTION

G. V. LEBOY, M.D. AND L. A. NIEFSKY, M.D.
CHICAGO, ILL.

THE first report of the influence of anticoagulants on coronary thrombosis was that of Solandt and Best in 1933¹ who used heparin successfully in experimental animals. Since 1945 many articles have appeared in the medical literature describing the use of Dicumarol for patients with recent myocardial infarction. The first patients to receive anticoagulant² therapy were selected because (1) "They had suffered repeated episodes of multiple thrombi in different areas of the coronary tree or the original thrombosis had propagated" or (2) "They had suffered repeated embolic phenomena either pulmonary or to other areas." It is apparent that the initial indications were based on analogy with the rationale of anticoagulant therapy in other forms of thromboembolic disease. Because of the beneficial effects of Dicumarol its use was not long restricted to patients with the complications noted; it was given to patients with myocardial infarction as a prophylaxis against such complications. Dicumarol is generally employed in preference to heparin because of the lesser expense and the convenience of the oral route of administration. All who have reported on its use have emphasized the indispensability of accurate prothrombin time determinations to control the dosage.

The incidence of thromboembolic complications in patients with recent myocardial infarction varies in different series of cases. The conflicting data are difficult to analyze and compare since the origin of emboli is seldom determinable with certainty. Hellerstein and Martin³ found thromboembolic lesions at autopsy in 45 per cent of 160 consecutive cases. Nay and Baines⁴ found thromboembolic complications in 37 per cent of 100 consecutive patients with myocardial infarction. Blumer⁵ found 16 per cent in his series of 175 patients. Conner and Holt⁶ reported 10 per cent in their series of 287 patients and Mintz and Kitz observed 9.9 per cent in a series of 572 patients with recent myocardial infarction. These data include not only thromboembolic phenomena arising in the heart but also phlebothrombosis, thrombophlebitis and so forth. The incidence of mural thrombosis of the endocardium is also difficult to ascertain. In autopsy series the reported incidence varies from 17 per cent to 83 per cent.⁸ It is evident from these reports that thromboembolism is an important complication of myocardial infarction. In all the reports of the results of anticoagulant therapy there has been an apparently significant reduction in the number of thromboembolic complications and in the general mortality rate. There has been as yet no report which includes suitable controls but such studies are now in progress at a number of centers under the auspices of the American Heart Association. It appears likely that anticoagulants will be used to an increasing extent in the treatment of patients with recent myocardial infarction.

From the Department of Medicine, Northwestern Medical School.
Received for publication Dec. 9, 1947.

The chief hazard with anticoagulant therapy is the development of a hemorrhagic state. It is customary to consider any abnormal bleeding tendency, hepatocellular disease, and renal insufficiency as contraindications to the use of Dicumarol. There are no reports in the literature of toxic effects of Dicumarol therapy other than the specific suppression of prothrombin production. Wright⁴ mentioned "The possibility that intimal hemorrhage might be a complicating factor (in coronary thrombosis) . . . but no evidence was obtained in this series, either clinically or pathologically, that this was of significance in any case. He also noted that "In no instance was it felt that Dicumarol influenced the rhythm or the rate of the heart directly." It occurred to us that the decreased coagulability of the blood resulting from Dicumarol (or heparin) therapy might affect adversely the course of the myocardial infarct. The early stages of these infarcts are characterized by hyperemia and hemorrhage, which is then followed by necrosis and organization with fibrosis. It seemed possible that the use of anticoagulants could accentuate the hemorrhagic stage of the infarct and thus prolong its resolution. Furthermore, there were no reports in the literature of side effects of Dicumarol which might be advantageous or disadvantageous to the infarcted heart. Such effects might involve facilitation or depression of autonomic reflexes arising in the infarcted myocardium.⁵ They might also lead to alterations in conduction leading to changes in the electrocardiogram.

The present study was undertaken to investigate the influence of Dicumarol therapy on the healing of experimental myocardial infarcts. Attention was directed particularly to (1) the mortality rate after the administration of Dicumarol, (2) the extent and character of the infarct, grossly and microscopically, (3) the evolution of the electrocardiographic changes, and (4) the behavior of the sedimentation rate. Anterior infarcts produced by ligation of the anterior descending branch of the left coronary artery were studied because it has been the experience in our laboratory, as well as elsewhere,^{6a} that these have a low immediate mortality—less than 25 per cent of the experimental dogs die within twenty-four hours and virtually none die later of cardiac failure. Mural thrombosis of the endocardium, or other obvious thromboembolic complications, have not been observed in any of the several hundred dogs with experimental myocardial infarction studied in this laboratory since 1938. On this account it was thought that in dogs any alteration in the mortality rate of experimental myocardial infarction in treated animals would be a primary effect of the Dicumarol, rather than a secondary effect due to the prevention of thromboembolic complications. Since uneventful recovery was the usual finding, deviations from the ordinary course should be easy to recognize.

METHODS

Healthy mongrel dogs of either sex were used. Control electrocardiograms were obtained, and blood was drawn for the determination of the prothrombin time, the hematocrit, and the sedimentation rate. Prothrombin time was determined by the method of Quick¹⁰ using a potent rabbit brain thromboplastin. The concentration of the thromboplastin was adjusted so that a value of 6 seconds was obtained with normal dog plasma. This value was assumed to rep-

resent 100 per cent prothrombin time. When longer values for prothrombin time were obtained during Dicumarol therapy they were expressed simply as per cent of the normal value of 6 seconds. This relationship is shown in Table I. In some instances prothrombin time was determined with 12.5 per cent plasma; the average normal value was 16.5 seconds with a range of 13 to 23 seconds. The sedimentation rate was measured in a Wintrobe tube with one reading made at one hour. The hematocrit was determined in the same tube by centrifuging at high speed to constant volume.

TABLE I. RELATIONSHIP BETWEEN PROTHROMBIN TIME IN SECONDS AND PER CENT PROTHROMBIN TIME

PROTHROMBIN TIME (SEC.)	PER CENT PROTHROMBIN TIME
6	100%
7.5	80%
9	67%
12	50%
15	40%
18	33%
21	29%

It is to be noted that per cent prothrombin time represents $\frac{\text{Normal control prothrombin time}}{\text{observed prothrombin time}} \times 100$. It does not refer to the dilution of normal plasma which would give the same number of second clotting time.

One half hour before operation each dog was given a subcutaneous injection of 10 m_g per kilogram morphine sulfate and 0.03 mg per kilogram atropine sulfate. General anesthesia was produced by the slow intravenous injection of solution of sodium pentobarbital approximately 30 mg per kilogram. A tracheal catheter was inserted and positive pressure ventilation with oxygen was obtained with a face mask and a water seal. With aseptic precautions the thorax and the pericardial sac were opened from the left side. A ligature was passed around the anterior descending branch of the left coronary artery between its origin and its first major branch. A satisfactory anastomosis was observed in every instance. Several cubic centimeters of penicillin solution (10,000 units per cubic centimeter) were placed in the pericardial and pleural spaces; the lung was re-inflated and the thorax was closed in layers.

When they regained consciousness the dogs that were to receive Dicumarol were given a first dose of 50 or 100 mg in a bolus of ground meat. The Dicumarol treated group were given the drug subsequently according to the following schedule:

Prothrombin time less than 15 seconds or more than 40 per cent prothrombin time: 50 m_g Dicumarol.

Prothrombin time from 15 to 25 seconds or between 40 and 24 per cent prothrombin time: 25 m_g Dicumarol.

Prothrombin time more than 25 seconds or less than 24 per cent prothrombin time: no Dicumarol.

Serial determinations of the prothrombin time, the hematocrit and the sedimentation rate and serial electrocardiograms were made on all dogs. Typical sample protocols are shown in Tables IV and V.

The animals were sacrificed at intervals of five to twenty two days after the ligation of the coronary artery. The time of death and the distribution of the groups are shown in Table II. The hearts were removed, cut open, and fixed in Kaiserling I solution. Subsequently the color of the tissues was developed in Kaiserling III solution and kodachrome photographs were obtained. Suitable blocks of tissue were removed for histologic examination.

RESULTS

Seven of the thirty-two dogs died within twenty-four hours after the production of coronary occlusion, giving an immediate mortality of 21.8 per cent (See Table II). There were no deaths attributable to cardiac failure after the

Autopsy The wound was well healed. There was a laceration of the lungs and pleural wall. There was no effusion. There was a light pericardial effusion. The fluid of which was serosanguineous in character. There was a small area of fibrosis overlying the region of the interventricular septum and some apparent thinning of the apex of the left ventricle. There was a small infarct.

The control electrocardiograms were analyzed with respect to the features consistently affected by myocardial infarction. The findings for twenty of the dogs that survived are shown in Table VI. After occlusion of the anterior descending branch of the left coronary artery changes resembling the human Q_1T_1 pattern were observed in fifteen of twenty one animals whose serial electrocardiograms were satisfactory for analysis. An example of the characteristic changes is shown in Fig. 1. The typical features occurred in 57 per cent of the control animals and in 61 per cent of those receiving Dicumolol. See Table VII. A. It is doubtful that this small difference is significant. The occurrence of changes in Q_1 , T_1 , T , T_2 and ST segments for the entire group (controls and treated) is summarized in Table VIII. The rate of evolution of the Q_1T_1 pattern in each

group is summarized in Table IX. There was no difference in the rate of evolution of the changes in Q_1 . In the animals that received Dicumarol inverted T_1 returned to normal on an average of one day later than in the control dogs. The significance of this difference also is doubtful. Arrhythmias (see Table VII B) were found more frequently in the electrocardiograms of the dogs that received Dicumarol. However it is our experience that when electrocardiograms are made daily in dogs, very few fail to show some arrhythmia after coronary occlusion. In the present experiment, tracings were not always made daily

during the first week when the transitory arrhythmias occurred. Bundle branch block occurred twice in the treated group, but this is not infrequent as a transient occurrence in dogs with myocardial infarction.

TABLE IX. EVOLUTION OF Q_1 , T_1 PATTERN IN SEVENTEEN ANIMALS SACRIFICED IN SECOND AND THIRD WEEK AFTER CORONARY OCCLUSION

Q_1	
Controls (6)	Five developed deep Q_1 One had no significant change in Q_1 One returned to normal on twenty-first day Four were sacrificed before change occurred
Dicumarol treated (11)	Six developed deep Q_1 Five had no significant change in Q_1 Five were sacrificed before change occurred One returned to normal on fourteenth day
T_1	
Controls (6)	Five developed inverted T_1 Five returned to normal by eighth day One had no significant change in T_1
Dicumarol treated (11)	Five developed inverted T_1 Four became normal by ninth day One died on eighth day T_1 inverted Six had no significant change in T_1

With one exception all the hearts removed at autopsy were found to have infarcts of the apical and anterior septal regions, with myocardial, subepicardial and subendocardial hemorrhage. The sole exception, Dog 19 a control, had no visible infarct. The ligature was in place and the coronary artery was occluded. Large anastomotic branches were easily seen connecting the occluded branch with the circumflex branch of the left coronary artery. There did not appear to be any significant, consistent difference in the size of the infarcts or the amount of hemorrhagic infiltration in the two groups of animals. This judgment is based on experience with more than 100 dogs' hearts with anterior infarction. Reproductions of kodachrome photographs of the control and the treated hearts sacrificed at similar times are shown in Figs. 2, 3, and 4. Pleural and pericardial adhesions occurred with equal frequency in each group of dogs. It is worthy of comment that the extent of these adhesions was much less than in our previous experience. The difference is most certainly due to the action of penicillin, applied topically, in preventing infection. Microscopic examination of representative sections was performed by Dr. William B. Waitman.* It was his opinion that there was no obvious difference between the healing infarcts in the treated animals and the controls.

Using the Quick method for prothrombin time and following the schedule of dosage of Dicumarol noted previously, it was possible to regulate the clotting activity of the blood in a satisfactory manner. Excessive dosage and the appearance of abnormally high values for prothrombin time occurred over holidays and week-ends when the usual daily dose was continued without laboratory control.

*Professor of Pathology, Northwestern Medical School.

Fig. 6—Right Dog 3 control sacrificed on the fifth day. Left Dog 4 control sacrificed on the fifth day received a total of 0 mg. Dicumarol maximum value for prothrombin time was 1 second. There is very little difference in the appearance of the two hearts.

Fig. 7—Right Dog 1 sacrificed on the seventeenth day received a total of 4 mg. Dicumarol maximum value for prothrombin time was 3.5 seconds. Left Dog 10 control sacrificed on the seventh day. There is no difference in the appearance of the two hearts.

In every instance in which abnormal bleeding occurred, the prothrombin time was longer than 25 seconds. In the control group the prothrombin time was shorter than the lower limit of normal during the first week after occlusion in four of the seven animals with satisfactory serial tests. (See Table IV.) Increased clotting activity of these dogs was apparent only when 125 per cent

Fig. 1—Right: Dog 17, sacrificed on the twenty-first day, received a total of 300 m. Dicumolol; the maximum value for prothrombin time was 65 seconds. Left: Dog 11, sacrificed on the sixteenth day, received a total of 125 mg. Dicumolol; the maximum value for prothrombin time was 30 seconds.

plasma was used for the determination. The variations in the sedimentation rate were not consistent and were of no importance in evaluating the course of experimental myocardial infarction. The hematocrit was a useful index of the extent of such anemia as developed.

SUMMARY

Myocardial infarction was produced in twenty-five dogs by ligation of the anterior descending branch of the left coronary artery. Fifteen of the animals were given Dicumolol in amounts equivalent to those used in the management of patients with recent myocardial infarction. There was no evidence that the altered coagulability of the blood affected the extent or the healing of the infarcts. Serial electrocardiograms did not show any consistent significant difference between the treated animals and the controls.

CONCLUSION

The use of the anticoagulant Dicumarol does not have any demonstrable deleterious influence on the healing of experimental myocardial infarction in dogs.

The authors wish to express their gratitude to Miss Ruth A. Trump, B.Sc., for her painstaking laboratory work.

THE EFFECTS OF DICUMAROL ON THE ELECTROCARDIOGRAM

SEYMOUR S. BALKIN, M.D., and ABRAHAM GOOTNICK, M.D.
MEMPHIS, TENN.

THROMBOEMBOLIC complications long have been recognized as a major hazard in the course of acute myocardial infarction^{1,2} Increased blood clotting tendency following myocardial infarction has been demonstrated repeatedly.^{4,5} Anticoagulant therapy with Dicumarol has been invoked accordingly by many clinicians as a prophylactic measure to neutralize the increased propensity to thromboembolism following myocardial infarction. In the past several years sufficient experience with this drug has accumulated to show substantial (in some reports even remarkable) reduction in thromboembolic catastrophes.^{7,8} Our own favorable experience thus far has been sufficiently persuasive to justify addition of controlled Dicumarol therapy to the routine regimen for every patient with acute myocardial infarction.

There are scattered references in the literature to the relative harmlessness of Dicumarol so far as the heart is concerned, Blumgart and co-workers showed that in dogs whose coronary arteries had been ligated Dicumarol had no adverse effects on the evolution of the infarction per se.^{9,10} In a field where electrocardiographic developments are depended on for evaluation of myocardial change it becomes important to determine whether any of the electrocardiographic changes are due to the drug taken. The purpose of this study was to establish whether Dicumarol per se has any effects on the electrocardiogram, and, if so, what these effects are.

METHODS

Dicumarol was given to forty-eight subjects. Of these, twelve were normal, with no discoverable evidence of cardiovascular disease and with repeatedly normal electrocardiograms (Group 1). Sixteen were patients with varying types of cardiovascular disease and a variety of abnormal electrocardiographic patterns which remained stable during preliminary observation (Group 2). Daily electrocardiograms were taken at each step of the progressive fall in the prothrombin level until prothrombin activity between 15 and 25 per cent of normal was attained. In several instances Dicumarol dosage was deliberately increased until prothrombin concentration fell to less than 10 per cent of normal so as to observe the effects of such dosage on the electrocardiogram. Inasmuch as in our cases of acute myocardial infarction anticoagulant therapy is continued until the patient becomes ambulatory, the effect of adequate Dicumarol medication continued for at least four weeks was observed in five of the normal subjects and in four of the subjects with cardiovascular disease (Group 1 and Group 2, respectively).

In addition we studied the serial electrocardiograms in fourteen of our patients with acute infarction who were on a Dicumarol regimen (Group 3) for evidence of possible Dicumarol effects, both during the period of Dicumarol treatment and following withdrawal of the drug.

From the Cardio-Vascular Section, Medical Service, Kennedy Veterans Administration Hospital.

Published with permission of the Medical Director, Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the author.

Received for publication March 5, 1948.

A separate group of six digitalized patients (Group 4) whose electrocardiograms had remained stable under prolonged observation were also treated with Dicumarol in the manner described to observe the possible modifying influence of the drug on the several degrees of digitalis effect.

In all subjects a preliminary study of renal function was done and a pretreatment prothrombin level was obtained. In the course of Dicumarol administration the drug effect was closely controlled with daily prothrombin level determination and toxicity was watched for by daily study for microscopic hematuria, examination of the skin for hemorrhagic extravasations, and inquiry about bleeding from gums, nose and gastrointestinal tract.

Aside from the maintenance dose of digitalis received by the six patients of Group 4 the only medication given was an occasional dose of aspirin and in Group 4 ascorbic acid and piperazine during the early stages of acute myocardial infarction.

Leads I, II, III, CF_1 , CF_2 and CF_3 were taken in all instances. Electrocardiograms were analyzed with respect to rhythm, auriculoventricular and intraventricular conduction, Q-T duration, RST level, and amplitude of auricular and ventricular components.

The Quick method was used to determine prothrombin activity. Each batch of thromboplastin substance was calibrated against a number of normal sera in several dilutions to minimize the errors of interpolation. Results were expressed as percentage of normal prothrombin activity.

RESULTS

In Groups 1 and 2 all electrocardiograms taken at successively lower prothrombin levels were substantially the same. An occasional tracing showed minimal changes in amplitude of T_1 and more rarely in amplitude of P component with the associated changes in rate. In the precordial leads minor changes in R/S ratio were seen attributable to slight shifting of the exploring electrode during successive tracings.

In those subjects maintained for several weeks on adequate doses of Dicumarol no appreciable change appeared in the electrocardiograms as a result of the prolonged medication.

Subjects given maximal doses of Dicumarol with depression of prothrombin to less than 10 per cent of normal showed no electrocardiographic effects of their hypoprothrombinemia.

The serial electrocardiograms of patients with acute myocardial infarction (Group 3) showed the expected progressive changes of healing infarction. The rate of progress did not differ materially from that observed in patients not receiving Dicumarol. Withdrawal of the drug during convalescence did not cause significant electrocardiographic changes in any of these cases. The residual electrocardiographic abnormalities in this small series fell within the expected range of late postinfarction patterns.

All of the group of patients whose electrocardiograms showed abnormalities attributable to digitalis (Group 4) retained the respective patterns unchanged by effective doses of Dicumarol and the electrocardiograms remained stable after withdrawal of the Dicumarol. In one of these patients occasional ventricular extrasystoles appeared in the course of the study and disappeared again when digitalis was withheld for two days. Dosage of Dicumarol was not changed during this interval and the electrocardiogram was not otherwise affected.

Questionable toxic effects were observed in only one of the subjects. On a morning when the prothrombin concentration was 15 per cent of normal the

patient reported coughing up (or possibly vomiting) a small quantity of blood streaked material. There was no associated evidence of bleeding in the skin, mucous membranes, or urine, and no change in blood pressure, heart rate, or red cell count. The electrocardiogram that day did not differ from previous and succeeding tracings. The patient was given 20 mg of synkavite intravenously, and Dicumarol was withheld. There were no further adverse manifestations.

SUMMARY

The addition of Dicumarol to the therapeutic regimen of patients with acute myocardial infarction suggested the investigation of the effects of the drug on the electrocardiogram.

The subjects of this study, forty-eight patients with and without heart disease and with a wide variety of electrocardiographic patterns, were maintained for a period on adequate doses of Dicumarol. Serial electrocardiograms taken during this period were analyzed.

No significant electrocardiographic deviation attributable to Dicumarol was observed in any of the subjects.

THE LIFE SPAN OF THE SICKLE CELL AND THE PATHOGENESIS OF SICKLE CELL ANEMIA

KARL SINGER, M.D. SIDNEY ROBIN, M.D. JOSEPH C. KING, M.D., AND
RONALD N. JEFFERSON, M.D.
CHICAGO, ILL.

THE mechanism responsible for the development of sickle cell anemia is not yet understood. Only relatively few Negroes who harbor the sickle cell trait are afflicted with this hemolytic syndrome. Recent *in vitro* studies of the sickling phenomenon in our laboratory¹ failed to demonstrate any fundamental difference between trait and anemia cells. When susceptible erythrocytes are suspended in a culture of *Bacillus subtilis* either sickling or oat cell formation occurs regularly after from five to fifteen minutes.¹ No distinct correlation could be detected between the number of sickle cells in the preparation or the rapidity and degree of the sickling process and the presence of either trait or anemia. Therefore it seemed conceivable that an additional qualitatively different factor might be operating in the production of the anemia.

As has been pointed out in a previous paper² the various hemolytic syndromes may quite generally be classified in two main groups. The first comprises all the disorders in which red cells are damaged by an extracorporeal mechanism (for example malaria). In the disorders belonging to the second group, premature disintegration of the erythrocytes is apparently caused by a primary abnormality of the stroma which may manifest itself morphologically (for example familial hemolytic jaundice). This classification is based on the so-called cross determination of the survival time of red cells. When normal erythrocytes transfused into a recipient with a hemolytic syndrome survive normally whereas the recipient's own red cells transfused into a normal person have a considerably shortened life span, an intracorporeal anomaly may be suspected. Contrariwise when normal red cells transfused into the patient with the hemolytic syndrome are as rapidly destroyed as the patient's own cells the presence of an extracorporeal mechanism may be assumed.

This paper deals with cross determinations of the survival time of sickle cells. Trait cells were transfused into patients with sickle cell anemia and anemia cells into healthy recipients displaying the sickle cell trait.

MATERIAL AND METHODS

The diagnosis of sickle cell anemia in patients used in this study was based on the presence of a marked or moderate anemia, increase of the reticulocyte count and elevation of the serum bilirubin besides a compatible clinical picture.

From the Department of Hematologic Research and the Department of Pediatric Research, Medical Research Institute, Michael Reese Hospital, and the Department of Pediatrics, Provident Hospital.

Received for publication Feb. 1, 1948.

tive and a positive sickle cell test. Almost all individuals considered to represent instances of the sickle cell trait had entirely normal hematologic findings except for the positive sickle cell test. Each patient had at least two complete hematologic examinations before being chosen either as donor or as recipient.

Hematologic Determinations—Five cubic centimeters of blood were obtained by venipuncture and transferred to a vial containing 4 mg potassium oxalate and 6 mg ammonium oxalate. From this oxalated blood the following determinations were regularly performed:

Hemoglobin Photoelectric method of Sheard and Sanford³ (Evelyn colorimeter), 100 per cent equals 15.6 Gm per 100 cc of blood.

Red Cell and White Cell Counts United States Bureau of Standards certified pipettes and hemocytometer used. Automatic shaker.

Hematocrit Centrifugation in Wintrobe type of hematocrit tubes for thirty minutes at 3,500 revolutions per minute.

Bilirubin in the Plasma Method of Malloy and Evelyn.⁴

Sickle Cell Test The rapid method of Singer and Robin.⁵

Furthermore, smears were prepared from capillary blood on cover slips and stained with Wright's stain. The reticulocyte count was obtained by the dry method.

Methods Used for the Determination of the Survival Time—Determinations of the survival time were done with the method of differential agglutination (Ashby technique⁶). Either O cells were transfused into recipients belonging to group A or B, or, if donor and recipient were of the same group, the donor's cells containing the N agglutinin were introduced into an M or MN recipient. Anti-M serum was then employed for agglutinating out the recipient's own cells in the follow-up studies. Anti-N serum was used only for typing and not for any quantitative evaluation on account of its known unreliability for this purpose.⁶

Typing for the Landsteiner blood groups was performed with potent sera prepared by the Serum Center.^{*} Testing for the M and N factors was done with sera supplied by the Certified Blood Donor Center.[†] In all patients the Rh factor was determined by means of a human anti-Rh serum of high titer.

Blood for transfusions was obtained by venipuncture and was transferred into a flask containing 50 cc of a modified acid mixture. Then the plasma was removed and replaced by a sufficient amount of a dextrose saline solution.[‡]

An adequate replacement transfusion was given to all anemic donors immediately after the bloodletting, thus more than compensating for the clinically undesirable loss of erythrocytes.

For the follow-up study of the transfused cells, the method of Young, Platzer, and Rafferty⁶ was found to be very satisfactory. Each recipient had at least two determinations of the nonagglutinable cells. Since very potent sera were used, the number of nonagglutinable cells never exceeded 50,000 per cubic millimeter.

*Michael Reese Research Foundation

†Jamaica, N. Y.

‡We are indebted to Dr. S. Levinson and Dr. A. Wolf of the Serum Center, Michael Reese Research Foundation, for their invaluable assistance in the processing of the erythrocytes.

Only young children (1 to 6 years old) were selected as recipients. Because of their small circulating blood volume a correspondingly small transfusion was found sufficient to result in a satisfactorily high addition of the donor's cells per cubic millimeter. Packed cells derived from 200 to 500 cc of whole blood were introduced, yielding an initial increase of 540,000 to 2 million cells per cubic millimeter in the recipient's total erythrocyte level. These initial values were established twenty-four hours after transfusion in order to avoid any significant inaccuracies due to incrementation of the circulating fluid volume, although it is realized that some of the transfused cells already may have been eliminated within the first twenty-four hours. After determining the starting points, follow-up studies were done twice weekly during the first month and from then on every week.

RESULTS

Transfusion of Trait Cells Into Patients With Sickle Cell Anemia—Experiments of this type were performed in three instances. The hematologic data of the respective donors and recipients are compiled in Table I. Fig. 1

Fig. 1—Transfusion of sickle cell trait cells into patient with sickle cell anemia expressed in per cent of surviving donor's cells

shows the curves illustrating the disappearance of the donor's cells. The percentage of the surviving cells is plotted against the number of days following transfusion. In all three instances the survival time of the trait cells was normal, with an average of 120 days. Thus trait cells when transfused into patients with sickle cell anemia have a normal survival time.

Fig. 2 shows the various red cell counts of one of the transfused recipients. These values represent the sum total of two populations of erythrocytes; that is, the recipient's own cells and the donor's cells. As can be seen from the illustrations, the patient's own cells were first hemolyzed much more rapidly than the transfused trait cells. After about thirty days there was an increase of the

TABLE I TRANSFUSION OF

patient's own cells. When the transfused cells had completely disappeared, approximately the same degree of anemia was present as existed before the transfusion. Similar results were obtained from an analysis of the total counts of the two other patients in this group.

Transfusion of Sickle Cell Anemia Cells Into Recipients With Sickle Cell Trait—Red cells from four patients with sickle cell anemia were transfused into three patients with sickle cell trait. In one experiment the red cells from two anemic patients both having blood group O were mixed and introduced into a single recipient, thus creating three different populations of red cells in this recipient. The hematologic data of the individuals used in this second group of studies may be found in Table II. Recipient 1 was a patient with non-deficiency anemia harboring the sickle cell trait. This patient had a hypochromic microcytic anemia with absence of target cells and showed a typical reticulocyte response with elevation of hemoglobin and erythrocytes after administration of iron.

Fig 3—Transfusion of sickle cell anemia cells into recipients with sickle cell trait expressed as per cent of surviving donor's cells

is too small to establish any definite correlation between the clinical severity of the donor's hemolytic process and the survival time. This problem requires further study, particularly in cases during hemolytic crisis.

DISCUSSION

The average life span of the red cell in dogs and human beings under physiologic conditions is approximately 120 days. This now must be considered as an established fact. By quite different methods for instance pigment studies in dogs with renal bilary fistula^{9, 11} and survival time determination after transfusion of variously labeled red cells (Ashby technique²¹ sulfhemoglobin,¹¹ radioactive nitrogen¹²) others have arrived at this same figure. British workers,^{13, 14} using the method of differential agglutination plotted the numbers of surviving cells against time in a diagram and found a linear type of disappearance. Normally a fixed fraction of those cells introduced at transfusion are removed in the unit of time (0.53 per cent per day). This straight line of decay depends on a property (age) of the transfused cells themselves. The finding of such a straight line of disappearance over a period of approximately 120 days may therefore be interpreted as the expression of erythrocytic disintegration by normal means.

If abnormal conditions exist these two criteria are altered: the survival time is considerably shortened and the graphs are either straight but steep or show a curved appearance. Such abnormal lines of decay are indicative of the presence of abnormal hemolytic mechanisms. By means of the cross determination of the survival time one may then gain better insight into the nature of these pathologic conditions. When normal erythrocytes transfused into a recipient with a hemolytic syndrome survive normally, whereas the recipient's own cells transfused into a normal person have a considerably shortened life span an intracorpuseular abnormality may be suspected. Contrariwise when normal red cells transfused into a patient with a hemolytic syndrome are as rapidly eliminated as the patient's own cells an indiscriminating extracorpuseular mechanism can be assumed.

Our experiments demonstrate that trait cells have a normal survival time and an almost straight line of decay when introduced into patients with sickle cell anemia. Anemia cells however when transfused into trait carriers are destroyed much more rapidly as can be seen from the abnormal graphs. Therefore the pathogenic principle operating in sickle cell anemia resides within the red cells themselves; no extracorpuseular mechanism can be made responsible for this hemolytic syndrome. Altman¹⁵ and Callender and Nickel⁸ reported that the longevity of normal erythrocytes in patients with sickle cell anemia is unaltered. The finding that trait cells also survive normally is of practical importance because these erythrocytes can be used safely for therapeutic transfusions.

Our investigations have established a fundamental difference between the survival time of anemia and trait cells. Since both types of cells show the sickling tendency the question arises whether this difference is related to a variable degree of the basic abnormality responsible for the sickling process or whether an additional structural alteration of the anemia cell may be involved. The following facts and observations require consideration in the evaluation of this problem:

(1) The well-known clinical fact that one does not encounter transitional types between sickle cell anemia and sickle cell anemia cases would support the existence of an additional pathogenic factor in the production of the anemia.

(2) Hahn and Gillespie,¹⁶ in 1927, made the significant discovery that distortion of susceptible corpuscles into sickle cells will take place only if the hemoglobin contained in the cells is in the reduced state. In vitro studies of the sickle cell phenomenon fail to show any clear distinction between trait and anemia if the sickling test is performed under conditions optimal for the reduction of hemoglobin. Neither with the gas chamber method of Hahn and Gillespie¹⁶ nor with the rapid method of Singer and Robin,¹ who used a broth culture of *B. subtilis* for the reduction of the oxyhemoglobin, could any definite correlation be detected between the number of sickling cells in the preparation or the rapidity and degree of the sickling process and the presence of either trait or anemia. The often demonstrable difference in the results between patients with anemic and trait cells with the moist stasis method¹ is probably caused by the increased number of nucleated red cells, reticulocytes, and white cells present in the anemia blood, only these cells consume oxygen, whereas mature red cells do not. As a proof of this interpretation, the observation¹ may be offered that when trait cells are mixed with the buffy layer of leucemic blood, sickling can almost immediately be elicited, although the unmixed blood may require more than twenty-four hours with the stasis method to achieve this result. On the other hand, intravascular sickling has been observed in anemic patients much more commonly than in trait carriers,¹⁸ and it has been speculated that blood destruction may be due to vascular stasis and obstruction of the capillaries by sickling red cells. Such a pathogenic mechanism, however, is unlikely because it would not account for the demonstrably different survival times of trait and anemia cells in the same patient.

(3) The experiments of Reinhard and co-workers¹⁹ also seem to retute the concept that a more pronounced sickling of cells in vivo may be instrumental in causing the anemia. These workers induced patients with sickle cell anemia to breathe high oxygen concentrations for periods of from eight to twenty days without detecting any inhibition of the rate of hemolysis, although a considerable decrease in the degree of intravascular sickling was noted.

(4) The finding that the pathogenic principle of sickle cell anemia resides within the red cells may lend itself to an explanation of the well known hemolytic crises which occur in this disorder. Murphy and Shapiro²⁰ suggested that the age of the red cell exerts an influence on its sickling tendency. According to these authors, normoblasts and reticulocytes are rarely seen in sickle form. This latter statement is not corroborated by our observations when optimal conditions for eliciting the sickling process are maintained. However, one may speculate whether the alterations of the stroma which occur with aging when superimposed on an already structurally defective cell, do not really lead to the massive disintegration of erythrocytes in a short period of time which is the outstanding hematologic feature of the crisis. After such an episode, the rejuvenation of the blood by many reticulocytes takes place. The

the same process repeats itself in relation to the average survival time of the cells in the circulation. This concept could be tested by correlating the time intervals between crises with the life spans of the red cells before and after such hemolytic exacerbations.

As can be seen from this discussion the known facts about the sickling phenomenon do not readily explain the pathogenesis of the anemia. Sickling is the expression of an abnormality of the stroma.¹ If together with this abnormality there exists an additional alteration in the exoskeleton,²² the cell structure becomes much more vulnerable to the vicissitudes of life in the circulation. Thus the survival time of the anemia cell is shortened. We are fully aware that this hypothesis is not yet based on any positive evidence. New experiments must be devised to furnish more factual support for this concept.

SUMMARY

The method of cross determination of the survival time of red cells was used for the study of the pathogenesis of sickle cell anemia. When normal erythrocytes transfused into a recipient with a hemolytic syndrome survive normally, whereas the recipient's own red cells transfused into a normal person have a considerably shortened life span, an intracorpuseular abnormality may be suspected. Contrariwise, when normal red cells transfused into the patient with the hemolytic syndrome are rapidly destroyed as the patient's own cells, the presence of an indiscriminating extracorpuseular mechanism may be assumed. In this study, trait cells were transfused into patients with sickle cell anemia and anemia cells into healthy recipients harboring the sickle cell trait.

Trait cells survive normally (120 days) when transfused into patients with sickle cell anemia, whereas the patients' own cells continue to be hemolyzed at a faster rate. Anemia cells when transfused into trait carriers have a shortened life span with an average of about one fourth of the normal. Therefore the pathogenic principle operating in sickle cell anemia resides within the red cells themselves; no extracorpuseular mechanism can apparently be made responsible for this hemolytic syndrome.

Trait cells can be used safely for therapeutic transfusions.

An analysis of the known facts about the sickling phenomenon shows that the sickling process, which is the expression of an abnormality of the stroma, does not lend itself to a satisfactory explanation of the pathogenesis of the anemia. The hypothesis is formulated that sickle cell anemia develops because of an additional alteration in the exoskeleton which is qualitatively different from the structural anomaly responsible for the sickling phenomenon.

INTRAGROUP INCOMPATIBILITY WITH RESPECT TO THE Rh BLOOD FACTORS AS A CAUSE OF MINOR HEMOLYTIC TRANSFUSION REACTIONS

ALEXANDER S. WIENER MD, FACP, FCCAP
BROOKLYN, N. Y.

THE work of Wiener and Peters¹ in demonstrating the role of the Rh factor of Landsteiner and Wiener^{2,3} in the pathogenesis of intragroup hemolytic transfusion reactions now has been amply confirmed.⁴⁻¹¹ This has brought about an important change in the practice of blood transfusion namely the inclusion of routine Rh testing along with A B blood grouping tests as a basis for the selection of donors for blood transfusion. The proper application of these tests has led to the virtual elimination of dangerous or major hemolytic reactions as a complication of transfusion. It gradually has become recognized moreover that Rh positive individuals also can be isosensitized because of the existence of more than one variety of Rh factor and the so called H₁ factors.¹²⁻¹⁴ Indeed these other blood factors are far less antigenic than the original rhesus factor (Rh₀) of Landsteiner and Wiener, so that such cases are quite rare. When isosensitization does occur it hardly ever reaches the degree characteristic of Rh or A B sensitization so that the antibodies usually are not demonstrable in the sensitized individual's serum and the reactions following transfusions of incompatible blood are mild and simulate pyrogenic reactions.¹ These minor hemolytic reactions occurring in Rh positive recipients are the subject of the present paper.

Paralleling the improvements in transfusion practice brought about by the discovery of the rhesus blood factors there also has been progress in eliminating pyrogens as a cause of nonspecific chills and fever following blood transfusions. For example at the Jewish Hospital of Brooklyn during the period 1945 to 1947 the total number of blood transfusions carried out annually increased from 1800 to 3800 yet the number of untoward reactions decreased from fifty eight to forty seven a drop in rate of reactions from 2.6 to 1.2 per cent. This is shown in Table I, together with the figures during a comparable period a decade ago.* The virtual elimination of pyrogenic reactions by meticulous care in preparing the blood transfusion apparatus together with the prevention of major hemolytic reactions by improvements in blood typing techniques, has served to bring to the fore the other class of reactions namely the minor hemolytic reactions which form the subject of this report.

From the Blood Transfusion Division of the Jewish Hospital of Brooklyn and the Serological Laboratory of the Office of the Chief Medical Examiner New York N. Y.

Presented at the Third International Congress for Blood Transfusion in Turin Italy 1948

Received for publication Feb. 25 1948

As will be seen from the Table I at the present time the bulk of the blood used at the Jewish Hospital of Brooklyn is obtained from the Blood and Plasma Exchange Bank of New York City so that this improvement is to be credited primarily to the admirable work of Dr. Lester J. Unger who is director of that blood bank which provides many thousand units of blood every month to hospitals throughout the country.

TABLE I COMPARISON OF INCIDENCE OF TRANSFUSION REACTIONS TODAY AND TEN YEARS AGO

YEAR	TOTAL NUMBER OF TRANS FUSIONS	BLOOD USED (UNITS)	TECHNIQUE OF TRANSFUSION			INCIDENCE OF REACTIONS	
			UNMODIFIED BLOOD (SYRINGE VALVE)	FRESH CITRATED BLOOD	BANK BLOOD *	NUMBER	PER CENT
1936-37*	1,209	—	950	259	—	95	7.9
1938*	976	—	360	616	—	22	2.3

THE Rh-H₁ BLOOD TYPES

In early studies on human anti-Rh sera it was soon found that in addition to the type corresponding to the original anti-rhesus serum (now designated anti-Rh₀),^{2, 3} which gave 85 per cent positive reactions on Caucasian blood, two other varieties of anti-Rh exist, namely anti-1h' (70 per cent positive)¹⁴ and anti-1h'' (30 per cent positive)¹⁵⁻¹⁷. The three anti-Rh sera determine three corresponding factors Rh₀, 1h', and 1h'' in human blood, which in combination give rise to eight types of blood instead of two, Rh positive and Rh negative.¹⁸

TABLE II SCHEME OF THE EIGHT Rh BLOOD TYPES

BLOOD CONTAINING FACTOR Rh ₀ (Rh POSITIVE)				BLOOD NOT CONTAINING FACTOR Rh ₀ (Rh NEGATIVE)			
DESIGNATION OF TYPES*	REACTIONS WITH SERA			DESIGNATION OF TYPES*	REACTIONS WITH SERA		
	ANTI 1h'	ANTI 1h''	ANTI Rh ₀		ANTI rh'	ANTI rh''	ANTI Rh ₀
Rh ₀	—	—	+	rh	—	—	—
Rh ₁	+	—	+	1h'	+	—	—
Rh	—	+	+	rh''	—	+	—
Rh ₁ Rh	+	+	+	1h'rh''	+	+	—

*Type Rh₁ contains the two factors Rh₀ and 1h', the name Rh₁ being short for Rh₀1h'. Similarly Rh₂ is short for Rh₀ and Rh₁Rh is short for Rh₀Rh₁.

Factor Rh₀ is written with a capital letter to indicate that it is the most antigenic and therefore the most important clinically, and also that it has a special genetic position. Factors 1h' and 1h'' are written with small letters to conform with their lesser clinical importance and also to indicate that these two Rh factors are on an equal plain genetically and serologically, very similar to the agglutinogens A and B. Thus, considering factors 1h' and 1h'' alone four types of blood are possible which are analogous to the four Landstemei blood groups. When factor Rh₀ is taken into account a double scheme of four types each results, as shown in Table II. Thus any one who understands the four blood groups immediately masters the eight Rh blood types.

To account for the heredity of the original Rh₀ factor, Landstemei and Wiener³ postulated the existence of a pair of allelic genes, *Rh* and *rh*. With the discovery of the eight Rh types, Wiener¹⁸⁻¹⁹ found it necessary to postulate

TABLE III EIGHT Rh TYPES AND THEIR TWENTY ONE GENOTYPES

Rh blood types	APPROXIMATE FREQUENCY IN ALC (%)	POSSIBLE GENOTYPES
rh	13.0	rr

the existence of a minimum of six allelic genes designated as R^0 , R^1 , R^2 , r , r' and r'' respectively. It will be noted that under this system the notations for genes and genotypes are different from the notations for the agglutinogens (or factors) and phenotypes so that ambiguity is avoided. In Table III are shown the genotypes corresponding to the eight phenotypes according to Wiener's theory of multiple allelic genes. The accuracy of this theory has been established by studies on a large series of families as well as by statistical studies on the distribution of the Rh blood types.^{10, 29*} For example in Table IV is given a summary of the author's studies²⁹ carried out on a total of 525 families with 948 children. In these studies only two seeming exceptions to the theory were encountered and both of these were proved to be due to allelism.

TABLE IV SUMMARY OF AUTHORS FAMILY STUDIES TO DATE

MATING	NUMBER OF FAMILIES	NUMBER OF CHILDREN OF TYPES							TOTAL
		rh	Rh	Rh	Rh Rh	Rh	rh	rh

The all inclusive between multiple alleles and completely linked genes was discussed in the first issue of the writer and others in relation to the heredity of the ABO group (Wiener & S. Blood Groups and Transfusion, Springfield, Ill. 1947 Charles C. Thomas, Inc. 1947 and 1948). The English school have now revised the discussion in relation to the Rh blood types.

Levine³⁰ and Javert³¹ demonstrated that Rh-negative blood specimens contain a special agglutinin designated H₁ by them because of its apparently reciprocal relation to Rh. Race and Taylor³² independently discovered an agglutinin which they called St, and showed that St was related to h' as M is related to N. Wiener and co-workers³³ have proved that H₁ and St are identical so that the designation St has been abandoned. Since the H₁ antigen first found was shown by Levine and Fisher to be reciprocally related to h', Wiener³⁴ suggested that it be designated as h₁'. As Fisher³⁵ pointed out, theoretically three H₁ factors are possible, corresponding to the three Rh factors. Actually, h₁' has been found³⁶ but convincing evidence regarding the existence of H₁₀ has not yet been published.[†]

Sensitization to the H₁ factors can cause clinical complications similar to those produced by Rh sensitization, namely intragroup hemolytic transfusion reactions and erythroblastosis fetalis. However, the H₁ factors are far less antigenic than the Rh factors, so that such cases are quite rare. For the same reason, H₁ antisera are much more difficult to procure than Rh antisera, and to date attempts to immunize H₁-negative donors in order to produce such antisera have met with little or no success. Yet H₁ antisera are necessary to resolve clinical problems caused by sensitization to factors other than Rh, and for the selection of H₁-negative donors to be used for transfusing patients sensitized to

TABLE V THE Rh H₁ BLOOD TYPES AND THEIR CORRESPONDING GENOTYPES

	-	+	Rh rh	12.0	R ⁰ r, R-R ⁰ , and R ⁰ r''
Rh ₁ Rh	+	+	Rh ₁ Rh	14.5	R ¹ R ⁰ , h ₁ 'r'', and r'l

*Tests which need not be made because the reactions in these combinations are invariably positive except for types rh'rh' and Rh₁Rh in the case of individuals carrying the alleles r⁰ and R⁰. Should these tests be done and negative reactions obtained there has been an error in technique and the entire examination should be repeated.

†These are phenotypes and the symbols have been selected so as to indicate what tests have actually been done and what reactions were obtained. For example type Rh₁ indicates that tests have been made only with sera anti-rh' and anti-rh'' and positive reactions obtained with anti-rh' and anti-Rh₀ and a negative reaction with anti rh'' on the other hand type Rh₁Rh₁ indicates type Rh₁ blood which also has been tested with anti h₁'' serum with which it gives a negative reaction.

*A second example of anti-h₁' has recently been found by Wiener and Peter.³⁷ The theoretical reactions of anti-H₁ sera have been presented by Fisher³⁵ and also by the writer³⁴ in previous papers. They are not included in the present paper because the writer has never encountered an anti-H₁ serum though such sera are said to have been found by others (Haberman S. Hill J. M. Everist B. W. and Davenport J. W. Jr. Blood in press).

one of the H_1 factors. Another important application of the Hr antisera is for a presumptive test for heterozygosity or homozygosity of Rh positive husbands of Rh negative prospective mothers who are known to be sensitized to the Rh factor. Still another application is in disputed paternity cases since the Rh H_1 tests considerably increase the chances of excluding a falsely accused man.

After a blood sample has been classified into one of the eight Rh blood types with the aid of the three Rh antisera anti rh' , anti rh , and anti Rh if indicated the blood can be subtyped with the aid of anti H_1 sera. The H_1 tests are done after the Rh tests in order to avoid unnecessary H_1 testing so as to conserve the rare and valuable H_1 antisera. Thus, only blood of types Rh_1 and rh need be tested with anti hr' serum and similarly only blood of types Rh and rh need be tested with anti hr'' serum. Other combinations uniformly give positive reactions, as shown in Table V, barring blood from the rare individuals who carry genes r' and R .^{38, 40}

The Rh H_1 subtypes are designated as follows:

$Rh_1 hr' -$ is called $Rh_1 Rh_1$
 $Rh_1 hr' +$ is called $Rh_1 rh$
 $rh hr' -$ is called $rh' rh$
 $rh' hr' +$ is called $rh' rh$

Similarly

$Rh_2 hr'' -$ is called $Rh_2 Rh_2$
 $Rh_2 hr'' +$ is called $Rh_2 rh$
 $rh hr'' -$ is called $rh rh$
 $rh'' rh' +$ is called $rh rh$

It must be emphasized that these designations refer to *phenotypes* not *genotypes*. Thus corresponding to phenotype $Rh_1 Rh_1$ two genotypes $R'R^1$ and $R'r'$ are theoretically possible while corresponding to phenotype $Rh_1 rh$ three genotypes, $R'r$, R^1R^0 , and $r'R^0$, are possible. Of these five genotypes R^1R^1 and $R'r$ are by far the most common and it will be seen that this is the basis for the selection of the phenotype names namely to indicate the most likely genotype. It is in this sense that anti hr' serum can be used to determine the *probable* genotype of type Rh_1 individuals and anti hr' serum to determine the *probable* genotype of type Rh_2 individuals.

From the foregoing it should be evident as has been pointed out by Wiener that the H_1 factors hold a serologic and genetic position in the scheme of the Rh Hr blood types analogous to that of the O factor in the less complicated scheme of the Landstamer A B O groups. Just as the O factor is by far the least antigenic among the A P O factors similarly the two H_1 factors are far less antigenic than the three (or four*) Rh factors. In this connection it may be mentioned that clinical sensitization to the O factor has occurred producing fetal erythroblastosis entirely comparable to cases of erythroblastosis caused by Hr sensitization.⁴

*The existence of a fourth Rh factor rh'' was predicted by Wiener⁴⁰ and confirmed by Callender and Race who designated it O'' .

MATERIALS AND METHODS

The cases forming the basis of this study were derived principally from the Blood Transfusion Division of the Jewish Hospital of Brooklyn, though a number of cases from other institutions were also included. Before every transfusion 10 cc of blood were obtained from the patient by venepuncture, 5 cc of which were mixed with dried oxalate powder, as for the Wintrobe Landsberg sedimentation test, and used for the grouping, Rh, and crossmatch tests, while 5 cc were placed in a dry clean tube and kept in the refrigerator for future reference. If any patient had a chill or other signs of reaction during or after the transfusion a second sample of blood was obtained without delay. The group and Rh type of the patient's and donor's blood specimens were verified, and the depth of color of the patient's serum (plasma) was compared with that of the pretransfusion sample. All glassware, syringes, and needles for these studies were sterilized in the hot air oven in order to avoid hemolysis due to moisture, and care was taken also when separating the clots to avoid artefacts caused by trauma to the clot. If the findings verified the original grouping and Rh report, and if there was no significant change in the color of the patient's plasma, the reaction was usually interpreted as pyrogenic and no contraindication was ordinarily considered to exist to further transfusions. In cases where the posttransfusion plasma was definitely darker than the pretransfusion sample, further studies were carried out to detect the possible presence of intra-group incompatibilities of an unusual type not provided against by the routine pretransfusion tests.

For simplicity in analyzing the results, the presentation will be confined to a statistical analysis of the groups, MN types and Rh Hr types of patients having reactions to transfusion, together with some brief clinical data concerning the reactions, and the results of tests for irregular isoantibodies in the patients' sera.

RESULTS

In Table VI are listed thirty-two cases of posttransfusion febrile reactions. In Cases 1 to 22 there was some clinical evidence of posttransfusion hemolysis while in Cases 23 to 32 there was no evidence of hemolysis.

It will be seen that the distribution of the A-B-O blood groups and MN types among the patients did not differ significantly from that occurring in the general population. On the other hand, while the distribution of the Rh Hr among the control cases (Cases 23 to 32) did not seem unusual, the distribution among the patients who had hemolytic reactions deviated strikingly. One can not help but be impressed by the large proportion of H₁-negative patients in the series—fourteen Rh₁Rh₁ and three Rh₂Rh₂ out of twenty-two cases. These results suggest that sensitization to the H₁ factors, h₁' and h₁" must have played a role in many of the reactions.

Attempts to demonstrate the presence of irregular H₁ isoantibodies in the sera of the Hr-negative patients failed in all but three of the cases in this series. In a fourth case (Case 14) which has been reported elsewhere,¹⁴ no H₁ antibody was found but instead a different irregular isoantibody reacting with about 14 per cent of all Caucasian blood and not corresponding to any hitherto described antibody. Of the three cases showing the presence of H₁ isoantibodies, in two (Cases 21 and 22) the specificity corresponded to h₁', while in the third (Case

*If any of the blood used for transfusion was left in the transfusion bottle smear and cultures were made for the possible presence of molds or bacteria. In only one case contamination proved to be the cause of reactions in our series.

†A sample of this serum was sent to Dr. A. E. Mourant who stated that it gave reactions corresponding to his own so-called Kell serum. Since in the original report¹⁴ on Kell antibody the serum was said to give only 7 per cent reactions instead of 14 per cent as obtained by us with anti-Si serum more work must be done before the two antigens may be assumed to be identical.

TABLE VI LIST OF CASES WITH FEBRILE REACTIONS TO BLOOD TRANSFUSIONS

CASE	PATIENT'S BLOOD TYPE	OTHER FINDINGS
1	A NRh Rh	Rise in icterus index
2	A MRh Rh ₁	hiccups in icterus index *
3	A Rh Rh	Rise in icterus index *
4	OMRh Rh	Rise in icterus index *

6	A MNRh Rh	Icterus index rose from 2 to 12 units
7	OMRh Rh ₁	Rise in icterus index all defined irregular antibody data fall in serum at times
8	A MNRh rh	Icterus index rose from 1 to 8 units
9	A MNRh Rh	Icterus index rose from 10 to 12 unit
10	A MNRh Rh ₂	Hemoglobinuria
11	ONRh Rh ₁	Cyrosis drop in hemoglobin
12	ONRh Rh	Icterus index rose from 2 to 4 units
13	OMNRh rh	Icterus index rose from 2 to 4 unit
14	AMNRh ₁ Rh	Shock drop in hemoglobin concentration irregular antibody anti S ₁ demonstrable by conglutination technique
15	A NRh Rh ₁	Rise in icterus index from 2 to 3 unit
16	OMRh Rh	Rise in icterus index
17	BMNRh	Rise in icterus index
18	OMRh Rh ₂	Strong anti hr agglutinin demonstrable in patient serum
19	A MRh Rh	Collapse severe hemoglobinuria
20	OMNRh Rh	Rise in icterus index from 4 to 12 unit dark urine
21	A BMNRh Rh	Strong anti hr agglutinin demonstrable in patient serum
22	BMNRh Rh	Patient's blood showed cranescent rise in hemoglobin concentration then a progressive fall terminating with patient death anti hr agglutinins in patient serum
23	ONRh Rh	No change in icterus index †
24	AMNRh rh	No change in icterus index †
25	ORh rh	No change in icterus index †
26	OMNRh rh	No change in icterus index †
27	ONRh Rh	No change in icterus index †
28	A MNRh Rh ₂	No change in icterus index †
29	A NRh rh	No change in icterus index †
30	A NRh rh	No change in icterus index †
31	OMRh Rh	No other data
32	OMRh rh	No other data

The posttransfusion plasma was darker to the eye than the pretransfusion plasma but no actual measurement of the icterus index was made

†The depth of color of the pre and posttransfusion plasmas appeared the same to the eye

18) the specificity proved to be hr'. This case of hr' sensitization was the first with demonstrable antibodies of this specificity to be encountered since the original report of Mourant²⁹ and therefore has been reported in detail elsewhere.³ With regard to the two cases of hr' sensitization with demonstrable antibodies the scanty clinical data available concerning these patients are presented below for the first time

CASE 21—This patient was brought to our attention by Dr. William Thallmer who had encountered difficulty in finding compatible blood for transfusing the patient because of the presence of an irregular isohemagglutinin. The patient was being treated for a spinal cord tumor.

The patient had had two normal children, the 20 year old son and 16 year old daughter were both well. She never had had any miscarriages or stillbirths.

On Feb. 17, 1939, the first exploratory operation had been performed. According to the patient he received her first blood transfusion in 1915. During that year the patient received three transfusions which were followed by chill. (The patient was not sure whether all the transfusions were followed by reactions.)

During the hospital admission of this study Nov. 18, 1941, the patient was given a transfusion of 500 cc. of group AB Rh positive blood following which he had a mild chill.

At the Montefiore Hospital, Bronx, N. Y., we are indebted to Dr. H. M. Zimmerman for his cooperation in obtaining a plentiful blood supply.

A second transfusion, this time of 300 cc of group A, Rh negative blood, was given Nov 14, 1947, and this was followed by a severe chill. A blood count done on Nov 14, 1947, showed a hemoglobin concentration of 9.5 Gm per 100 cc, RBC, 3.30 million per cubic millimeter, WBC, 14,100 per cubic millimeter, polymorphonuclears, 76 (six band forms), lymphocytes, 23, and monocytes, 1. A repeat blood count of Dec 10, 1947, showed a hemoglobin concentration of 10 Gm per 100 cc, RBC, 3.70 million, WBC, 7,600, polymorphonuclears, 4 (four band forms), lymphocytes, 25, monocytes, 5.

Our own studies on the patient's blood showed her to belong to group AB, subgroup A,B, type MN, and type Rh,Rh_i. Since the patient was H_i negative (or more exactly, h' negative), this suggested that the irregular antibody in the serum might be an anti h' agglutinin. In fact, titrations of the patient's serum at body temperature proved that powerful anti h' agglutinin was present, the titer of the serum for homozygous h' positive blood (for example type hh) being approximately 250 units, while the titer for heterozygous h' positive blood (for example type Rh,rh) was about half as high. However the serum exhibited a tendency to clump most if not all blood specimens of type Rh,Rh_i, particularly when the mixtures were allowed to cool. Titrations at refrigerator temperature showed that this was due to the presence of a strong autoagglutinin. This interfering antibody could be removed by repeated absorptions with type Rh,Rh_i of any blood group and in that way it was possible to obtain a satisfactory anti h' reagent for subtyping Rh_i and type rh' individuals. Some of the tests indicated the possible presence of still a third abnormal antibody in the patient's serum, and, while this antibody was not studied carefully, in view of the patient's subgroup (A,B) the likelihood is that its specificity was anti O.

CASE 22—An intern at a hospital in New York City consulted us concerning the following transfusion problem.

The patient a woman, was said to have pernicious anemia with cardiac complications. The pregnancy history was not known, but the patient was said to have been transfused several times approximately a year previously. On admission to the hospital on Nov 7, 1947, the patient's condition was critical, the blood having a hemoglobin concentration of only 2 Gm per cent, with RBC 1.1 million per cubic millimeter and 0.4 per cent reticulocytes on the smear. The patient was given an immediate transfusion of a total of 1,500 cc of blood and placed on liver therapy. A blood count of November 10 showed that the hemoglobin concentration had risen to 8 Gm per cent, with RBC 2.4 million and 0.4 per cent reticulocytes on the smear. By November 12 the hemoglobin concentration had fallen to 7 Gm per cent with RBC 1.48 million, though there were now 4.8 per cent reticulocytes on the smear, and this time the icterus index was found to be 32 units. By the next day the hemoglobin concentration had dropped to only 4 Gm per cent with a red blood cell count of 1.0 million while the icterus index rose to 75 units. The patient was then given another transfusion of 500 cc of blood, this time without any reaction. The following day the patient was chills and blood was referred to us for study.

In the blood typing tests the following reactions were obtained

REACTIONS WITH ANTISERA OF SPECIFICITY							
A	B	M	N	rh'	rh''	Rh ₀	hr
-	++±	++±	$\frac{1}{10}(++)$	++	$\frac{1}{10}(+)$	++±	$\frac{1}{10}(++)$

These results indicated that the patient belonged to group B, type M, type Rh,Rh_i, b that her body also contained some group B, type MN, type Rh,Rh blood, probably resulting from the transfusion received the day before. This led us to entertain the likelihood that a developing sensitization to the hr' factor was the cause of the rapid elimination from the patient's body of the 1,500 cc of blood she had received the week previous. Examination of the patient's serum did reveal the presence of an irregular agglutinin.

most active at body temperature, which did not clump her own blood cells or blood from other type Rh_hRh_i individuals of groups B and O confirming the prediction that she was sensitized to the hr' factor. The hr' agglutinin was weak however so that while blood specimens homozygous for the hr' factor, for example, types rh and Rh were clumped up to dilution 1:4, blood heterozygous for the hr' factor for example types Rh_hrh and Rh Rh_i was not clumped or only feebly clumped. The low titer of the hr antibody explained the continued presence in the patient's circulation of some of the type Rh_hRh blood received by transfusion the day before.

In view of these findings it was advised that for further transfusions to this patient only hr negative (type Rh Rh_i) group B blood be used. Unfortunately the patient died before another transfusion could be given.

The cases listed in Table VI, and especially the two cases just described demonstrate that H₁ sensitization may pose a serious problem where patients require repeated transfusions over a long period of time. As has been demonstrated elsewhere,⁴⁸⁻⁵¹ the wide spacing of the transfusions is probably the most important factor in the development of isosensitization. For example two or more transfusions spaced widely apart as in the cases just described are much more likely to induce sensitization than a large series of transfusions given within a short period of time. In fact this principle has been applied successfully in the production of anti Rh sera of specificities Rh₀, rh' and rh'' though we have not yet succeeded in producing anti H₁ sera in this manner. Two of our type rh donors,⁴⁸ both of group AB type N formed agglutinins of specificity anti M as well as antibodies of specificities Rh₀ and rh'' when injected with OMRh_hRh blood.⁵⁰ These observations lead one to draw certain analogies between the three systems of blood group and type antigens as shown in Table VII.

TABLE VII ANALOGIES AMONG A B O M N AND Rh Hr SYSTEM OF ANTIGENS

For simplicity the rarer types A₂, M, N and so on are not included in this table.

†The common antigen shared by blood containing agglutinin A or B or both.

‡The antigen shared by agglutinogens O and A but absent from agglutinogens A and B.

§Convincing evidence concerning the existence of the theoretically possible antigen Hr has not yet been published.

Recently we were consulted concerning a case which offered an unusual problem of interest in connection with the subject under discussion. The patient was a boy requiring repeated transfusions over a period of years, and we were asked for advice in the selection of donors in order to avoid if possible the development of isosensitization. Grouping and Rh Hr tests on this patient and the parents gave the results shown in Table VIII. As can be seen this patient offered a problem practically impossible to solve. Since he belonged to type rh, his blood lacked the Rh₀ agglutininogen and so he had to be given Rh negative blood. At the same time, he was hr' negative and it was desirable also to avoid the possibility of H₁ sensitization. Unfortunately the only type of blood which is both Rh₀ negative and hr' negative is blood of the rare type rh'rh' identical

TABLE VIII

BLOOD OF	GROUP	M N TYPE	Rh Hr TYPE	
			PHENOTYPE	GENOTYPE
Father of patient	A ₁	N	Rh ₁ Rh ₂	rR ^r
Mother of patient	A ₁	MIN	Rh ₁ Rh ₁	Rir ^r
Patient	A ₁	N	rh'rh'	r'r

with the patient's blood and with an incidence of only 1 in about 10,000 in individuals. In addition, the patient belonged to type N, which has a frequency of 20 per cent, so that a completely compatible donor, even using group O donor, would occur only once among about 50,000 individuals. In this case, therefore, we had to be content to take into account only the most antigenic of the three factors Rh₀, hr', and M, and so ordinary type 1h donors of group A were used. Incidentally, the case offers an interesting example of the genetics of the Rh Hr types as shown in Table VIII.

COMMENT

Our attention was first called to the possibility of hemolytic transfusion reactions caused by isosensitization to the H₁ factor by a patient seen in 1944. In this case, reported by Speck and Sonn,⁴⁴ the patient, who belonged to type Rh₁Rh₁ and group AB, had a hemolytic reaction during a post partum transfusion of type 1h, group AB blood. However, as in most of the cases described in this paper, abnormal isoantibodies were not clearly demonstrable in the patient's serum. More recently Sussman⁴⁵ has reported a case of hr' sensitization by transfusion in which the patient's serum contained strong isoantibodies which, however, were demonstrable only by the conglutination technique.

In view of our findings it is necessary for all hospitals giving large numbers of transfusions, especially to patients requiring repeated transfusions spread over a long period of time, to have available not only type 1h but also type Rh₁Rh₁ and type Rh₂Rh₂ donors, at least of group O, for use for isosensitized patients. For the present it is still not practicable to carry out H₁ tests on all patients requiring transfusions for selecting donors. Since the Hr factors are only poorly antigenic, we ordinarily disregarded them in the pretransfusion tests. Only when a patient has had a reaction do we test for the H₁ factors, and if such a patient is found to belong to type Rh₁Rh₁ or type Rh₂Rh₂, the precaution is taken to use only Hr-negative donors for future transfusions. Ideally, however, the tests should eventually become part of the routine pretransfusion selection of donors, not only to prevent reactions but also to prevent sensitization, especially of women who might subsequently have children with erythroblastosis caused by H₁ sensitization.⁴⁶

SUMMARY

The introduction of routine Rh testing along with blood grouping tests on a basis of the selection of donors for transfusions has served to eliminate the danger of serious hemolytic reactions. Simultaneously there has been a reduction in the frequency of posttransfusion chills, as a result of the perfection of methods of eliminating pyrogenic materials from blood transfusion apparatus. Thus at the author's institution the frequency of febrile reactions dropped in

79 per cent in 1936 to 29 per cent in 1939 and to only 12 per cent by 1947. The virtual elimination of pyrogenic reactions has served to make more prominent another class of hemolytic reactions—usually only of minor severity, occurring in Rh positive patients becoming sensitized by repeated transfusions given over a long period of time.

In a series of twenty three Rh positive patients having febrile reactions and at the same time showing evidence of posttransfusion hemolysis as many as seventeen were H₁ negative (fourteen Rh₁Rh₁ and three type Rh Rh) while among ten patients with febrile reactions but without evidence of hemolysis none were Hr negative. This indicates that H₁ sensitization plays a predominant role as a cause of hemolytic reactions in Rh positive patients. H₁ antibodies were clearly demonstrable in the sera of only three (two anti hr' and one anti hr') of the seventeen presumably sensitized patients. This indicates that H₁ sensitization, when it occurs at all, is usually mild in degree. This conforms with the usual mild course of reactions caused by H₁ sensitization in that such reactions are usually so harmless that they are passed off as ordinary pyrogenic reactions. However, that such reactions may sometimes endanger the life of the patient is demonstrated by the fact that one of the three patients with demonstrable antibodies died.

While routine pretransfusion H₁ typing is still not practicable one should at least investigate every febrile reaction for evidence of hemolysis. If hemolysis has occurred even though the patient is Rh positive Hr tests should be done and if the patient is found to be Hr negative only H₁ negative blood of a compatible blood group should be used for future transfusions. If Rh negative patients have reactions despite transfusions of type rh blood, one should search for other sensitizations particularly against the M factor. Particularly difficult to solve will be instances of multiple sensitization one of the most common examples of which in the author's experience is double sensitization to factors Rh and M.

Eventually blood transfusion practice should include suitable precautions to avoid sensitization against the Hr factors as well as the Rh factors particularly in the case of women in order to avoid the birth of babies with erythroblastosis caused by H₁ sensitization.

INFECTIOUS HEPATITIS INADVERTENTLY TRANSMITTED WITH THERAPEUTIC MALARIA

CAPTAIN MARTIN H. SMITH AND CAPTAIN JAMES W. HALL
MEDICAL CORPS, ARMY OF THE UNITED STATES

ACUTE hepatitis resulting from the transmission of an ieterogenic agent in blood and blood products has been described frequently in recent years. The purpose of this paper is to call attention to a particular mode of transmission. It has been recognized that an ieterogenic agent might possibly be transferred when patients are inoculated with therapeutic malaria. However, the hazard has not received sufficient emphasis to cause suitable precautions to be taken in many hospitals using this type of fever therapy. The menace is particularly great since the usual efforts to perpetuate a strain of malaria also mean serial transmission of the ieterogenic agent.

The ieterogenic agent has been shown to be a virus.² Havens¹⁰ has presented evidence that the ieterogenic agents of infectious hepatitis and homologous serum jaundice are different viruses. He bases his argument primarily on the fact that the incubation period of the former is 15 to 34 days and of the latter, 58 to 134 days. In 1943 Beeson¹ reported seven cases of jaundice occurring one to four months following transfusions. Other authors⁵ have reported a mean incubation period in homologous serum jaundice of 100.1 days. According to the criteria of Havens, the cases to be presented in this paper would be classified as infectious hepatitis rather than homologous serum jaundice. The most common sources of infection have been contaminated lots of yellow fever vaccine,^{2,4} pooled plasma,^{6,8} and mumps convalescent plasma.³ In 1947 Chalmers⁹ reported on 490 patients who had been given therapeutic malaria. Of this group, thirty-six cases developed jaundice and evidence of liver damage. He felt that his cases were suggestive of the transfer of an ieterogenic agent at the time of inoculation with malaria. In Chalmers' series ninety-nine patients were mosquito inoculated and none of them developed jaundice.

We shall describe in this paper six patients who received serial inoculations of the same strain of quartan malaria and subsequently developed severe jaundice and marked evidence of hepatocellular damage. These cases were discovered when one of the convalescing patients was received by one of the authors in an interhospital transfer, consequently, full study of these patients was undertaken only after they had begun the clinical recovery phase. For this reason all the laboratory data that might be desired were not obtained during the acute phase of the illness. The patients had been given malarial fever therapy in treatment of central nervous system syphilis. They were all men whose ages ranged from 29 to 51 years, and all were considered good risks for fever therapy with malaria.

Published with the permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

Received for publication March 18, 1948

Prior to inoculation there was no clinical evidence of liver disease, and no hepatic drugs were given during hospitalization. The incubation period in this series ranged from 20 to 43 days, with an average of 32.5 days. The estimated incubation period in some instances is probably longer than the actual period since the patients rarely expressed any subjective symptoms. The sequence of, and the time interval between, the inoculations will be stressed in the case reports. The results of the bromsulphalein tests were obtained by using the 5 mg per kilogram dose. The standard technique for inoculation with malaria at this hospital has been to give 5 cc of donor blood intravenously and 5 cc intramuscularly.

REPORT OF CASES

CASE 1—This patient (P W) was probably the original source of the virus in the series. All persons who had received this strain of malaria previously showed no evidence of infectious hepatitis. The six subsequent patients inoculated did develop marked evidence of infectious hepatitis. In later questioning P W admitted that two years earlier in the South Pacific several of his tent mates had developed jaundice and that he had had an episode of malaise with vague abdominal distress. He had had no further symptoms until the present illness. The patient was a 34-year-old white man who was inoculated with malaria May 5, 1947. His fever was terminated June 29, 1947, after fifty-two hours above 104°. At no time was jaundice noted nor were symptoms of hepatitis present. During the course of fever the red blood cell count fell from 5,210,000 to 4,100,000 per cubic millimeter. The cephalin flocculation test 139 days after inoculation was positive plus 4 after twenty-four hours and on the same date the bromsulphalein test showed 9.5 per cent retention after thirty minutes. The patient has continued free of any hepatic symptoms.

CASE 2—J I, a 41-year-old white man, was inoculated May 16, 1947, with blood from P W (Case 1). The patient complained of malaise and anorexia forty-one days after inoculation, and on July 5, 1947, jaundice and symptoms of hepatitis had become so severe that the malaria was terminated. During the course of fever the red blood cell count fell from 5,400,000 to 3,230,000. A leucopenia did not develop. On the forty-eighth day following inoculation the icterus index was 100 units and serum protein was 8.25 Gm per 100 cc with albumin 3.45 Gm per 100 cc and globulin 4.8 Gm per 100 cubic centimeters. The temperature curve did not fall to the base line between the spikes of fever and after the malaria was terminated a low grade temperature elevation continued for twenty days.

CASE 3—F S, a 40-year-old white man, was inoculated with malaria on July 2, 1947, with blood from J I (Case 2). He complained of nausea and vomiting seventeen days after inoculation, and two days later marked jaundice appeared. Abdominal pain was present and there was tenderness at the right costal margin though the liver could not be palpated. His fever was terminated twenty-six days after inoculation. The red blood cell count did not fall during the fever therapy possibly because of dehydration. Between spikes of fever due to malaria the temperature curve did not return to the base line. The icterus index twenty-one days after inoculation was 90 units, at seventy-seven days 159 units and at 109 days 13 units. The cephalin flocculation test seventy-seven days after inoculation was positive plus 4 at the end of twenty-four hours and thirty days later had become negative. The bromsulphalein test eighty-five days after inoculation showed 37 per cent retention at the end of thirty minutes.

CASE 4—W B, a 51-year-old white man, was inoculated with malaria on July 29, 1947, with blood from F S (Case 3). Jaundice appeared thirty-eight days after inoculation and termination of fever was begun. The patient had twenty-six hours of fever above 104°. The initial red blood cell count of 4,830,000 and hemoglobin of 13.2 Gm fell during fever to 3,900,000 and 9.2 Gm respectively. The white blood cell count was never above 7,000 nor

below 5,400 The bromsulfalein test ninety four days after inoculation showed thirty per cent retention at the end of thirty minutes Seventy five days after inoculation the icterus index was 9.6 units and the cephalin flocculation was positive plus 4 after twenty four hours At 111 days after inoculation cephalin flocculation was still positive plus four after twenty four hours

CASE 5—C H, a 39 year old white man, was inoculated with malaria on July 29, 1947, with blood taken from F S (Case 3) Jaundice appeared forty three days after inoculation and was accompanied by severe abdominal pain, eructation, nausea, and vomiting These symptoms were so severe that termination of malaria was necessary forty eight days after inoculation During this illness the red blood cell count fell from 4,550,000 to 3,330,000, and the hemoglobin from 13.2 to 10.6 grams A leucopenia did not develop in this patient Bed rest was required for three weeks after malaria was terminated The bromsulfalein test showed 25 per cent retention at thirty minutes seventy three days after inoculation Seventy five days after inoculation the icterus index was still 16.7 units and cephalin flocculation was positive plus 4 after twenty four hours

CASE 6—R T, a 34 year old white man, was inoculated with malaria from F S (Case 3) on July 29, 1947 Jaundice appeared twenty seven days after inoculation, and the patient appeared acutely ill with sustained fever and gastrointestinal distress The fever did not fall below 101° between the malaria spikes Malaria was terminated thirty days after inoculation At the peak of the acute illness, the previously normal red blood cell count and hemoglobin fell to 3,590,000 and 13.2 Gm respectively The white blood cell count fell to 3,500 Sixty three days after inoculation the cephalin flocculation was positive plus 4 at the end of twenty four hours Sixty six days after inoculation the bromsulfalein test showed 29.9 per cent retention at the end of thirty minutes, and cephalin flocculation was positive plus 2 at the end of forty eight hours Cephalin flocculation was negative after forty eight hours 111 days after inoculation

CASE 7—W S, a 43 year old white man, was inoculated with malaria from C H (Case 5) on Sept 5, 1947 Jaundice appeared twenty seven days after inoculation and the patient complained of abdominal pain, anorexia, nausea, and vomiting The fever curve rarely fell below 100° between the malaria spikes A tender liver edge was palpated 3 cm below the right costal margin Termination of malaria was necessary thirty one days after inoculation The patient had a long convalescence with continuation of gastrointestinal symptoms Before inoculation with malaria the red blood cell count was 5,210,000 and the hemoglobin was 16.4 grams During the acute phase of illness the red blood cell count fell to 3,280,000 and the hemoglobin to 10.6 grams The white blood cell count remained normal A low grade fever continued for three weeks after termination of malaria Thirty five days after inoculation there was 39 per cent bromsulfalein retention after thirty minutes Thirty eight days after inoculation the icterus index was still 14.3 units The cephalin flocculation test was positive plus 2 at forty eight hours, seventy one days after inoculation

COMMENT

The consecutive development in these patients of evidence of hepatitis which followed serial inoculation with malaria is significant The fact that all the findings could have been caused by a virulent strain of malaria is acknowledged. However, this same strain of malaria had been used on a great number of other individuals in this hospital without such ill effects It is felt that the only logical explanation is that an icterogenic agent was transferred at the time of inoculation with malaria According to Havens' classification, the short incubation period in this series is more compatible with infectious hepatitis than with homologous serum jaundice The transfer of an icterogenic agent, therefore, constitutes an additional hazard in malarial fever therapy In addition to the

obvious danger to the patient this complication necessitates early termination of the fever. The patient who can be a source of the heterogenic agent should not have his blood passed to the next patient, and will probably be a bad risk for fever therapy with malaria as well. It would seem that the best way to avoid this hazard is to perform liver function tests routinely before fever therapy is begun.

SUMMARY

Six patients are presented who consecutively developed evidence of hepatitis following inoculation with therapeutic malaria. An additional patient is described who probably served as the original source of the heterogenic agent in this series. It is believed that infectious hepatitis was inadvertently transmitted with therapeutic malaria.

STUDIES IN HODGKIN'S SYNDROME

VII NITROGEN MUSTARD THERAPY

ROBERT P. ZANES, JR., M.D.,* CHARLES A. DOAN, M.D.,† AND
HERMAN A. HOSTER, M.D.‡
COLUMBUS, OHIO

THE occurrence of leucopenia in individuals exposed to nitrogen mustard gas was recognized during World War I.¹ It was not until World War II however that extensive studies concerning the cytotoxic properties of nitrogen mustard compounds were undertaken. A specific affinity of the *bis* and *tris* (β chloroethyl) amines for rapidly growing and regenerating tissue in general and a particular susceptibility of the hematopoietic and lymphoid systems to the cytotoxic action of these substances have been described.^{1, 2, 11} The therapeutic trial of methyl-*bis* and *tris* nitrogen mustard compounds in lymphomatous and certain other neoplastic diseases followed. Gilman and Philips¹⁰ and Rhoads⁴ have summarized the historical background as well as the chemical, pharmacologic, and physiologic properties of this group of chemical agents.

Clinical studies using the *tris* and the *bis* (β chloroethyl) amines have been carried on by a number of investigators. Patients with a variety of neoplasms exclusive of the hematologic dyscrasias have been treated with these compounds but results in most cases do not appear to justify their continued use. The most encouraging results described to date have been observed in Hodgkin's disease.¹²⁻¹⁵ It is generally agreed, on the basis of preliminary published data, that remissions which are induced by this therapy are temporary, lasting 0 to 8 months, and that the clinical results achieved are comparable in many ways to those produced by roentgen rays.^{5, 9, 12, 14, 15} Kainofsky has restated an opinion shared by many investigators⁹ that roentgen therapy is advisable in early localized Hodgkin's lesions and local extensions, and that nitrogen mustard may be more effective in generalized Hodgkin's disease, early and late and in cases characterized by severe systemic intoxication.

The only persistent systemic toxic effect of the halogenated amines reported at so-called therapeutic dose levels is a more or less severe but transient damage to hematopoietic and lymphoid tissues. Leucopenia, thrombocytopenia, and moderate anemia appear in a large percentage of cases under these conditions. A decrease in the number of formed elements in the peripheral blood becomes apparent three to four days after the beginning of therapy and continues for approximately three weeks. Serial bone marrow studies have revealed progressive destructive hypoplasia consistent with the peripheral blood findings. Dur

The authors are indebted to Dr. B. K. Wiseman for permission to include a number of his cases in the present series

Received for publication May 6 1948

ing the fourth week regeneration takes place^{6, 8, 11}. The first cellular elements to be depressed are the lymphocytes followed in a few days by an absolute panleucopenia with a decrease in the number of polymorphonuclear leukocytes.

Jacobson and associates¹ have described a left shift in the lymphocytes with the appearance of abnormal forms. Similar qualitative abnormalities have been noted in the monocyte series. Both cell types return to normal within two or three weeks. The reticulocytes of the peripheral blood are reduced during the first week to less than 0.1 per cent and thrombocytopenia develops during the third week after treatment. However, in spite of this obvious and extensive damage to the bone marrow, the great majority of patients revert promptly to a relatively normal hematologic equilibrium within a few weeks after therapy depending on the degree of normality of the marrow before therapy was instituted. Folic acid, Pentnucleotide, iron and whole blood do not ameliorate the toxic effects produced.

The present report is based on the treatment of thirty-one patients with Hodgkin's disease with forty-four courses of the methylbis (β -chloroethyl) amine hydrochloride. In every case the biopsy diagnosis of Hodgkin's disease was confirmed by two or more pathologists before treatment was begun. Two patients received three, nine received two and twenty received one course of therapy. For the most part the choice of patients in this series followed the criteria of Karnofsky⁹; in addition patients were selected who presented evidence of local extensions of the disease and who had not responded to roentgen therapy. Serial peripheral blood studies were made in all patients supplemented whenever practicable by sternal marrow examinations. The survival staining technique was used in all differential blood cell estimations.

Each patient was given 0.1 mg of HN₂ per kilogram body weight for five days with the exception of the seven individuals who were given a double dose on two consecutive days and a single dose on the third day. Each dose was dissolved in 10 cc of normal saline and injected immediately via the tube through which normal saline was being administered intravenously to the patient. From 200 to 500 cc of saline were infused during each injection of HN₂.

In evaluating the results obtained after nitrogen mustard therapy, a remission was defined as a decrease in unfavorable symptoms ascribed to the disease and an objective regression of the disease as measured by roentgenologic and hematologic findings and physical examination.

RESULTS

A summary of the results is presented in Table I. The average remission time following HN₂ in this series was 2.8 months. The longest remissions were four, five and six months respectively. Some of these cases are still in remission at the time of writing. Ten patients included in this series have expired. The remainder have been maintained on subsequent courses of nitrogen mustard and/or radiation therapy.

An analysis of the results of treatment was made with special reference to the therapy used previous to the initial course of mustard; the specific indica-

tions for HN_2 , and the subsequent activity and treatment of the disease. The case numbers used refer to Table I. The patients who obtained benefit from nitrogen mustard therapy were divided into four groups. The first group includes one patient who had received no previous therapy of any kind (Case 29) and those patients who had previously experienced remissions following roentgen radiation (Cases 2, 12, 16, 23, 24, and 25). Improvement was observed in all members of this group after nitrogen mustard. The second group (Cases 5, 8, 10, 20 and 30) includes patients with widely disseminated Hodgkin's disease manifest by severe systemic intoxication but no demonstrable localized foci of activity. Following treatment with HN_2 remissions occurred and later recurrences of the disease were localized and responded readily to roentgen ray therapy. The third group consists of patients (Cases 3, 7, 9, 11, 14, 18, 22, and 31) who had received radiation over localized areas of activity without any beneficial effect and were considered to be roentgen ray resistant. These patients demonstrated significant clinical improvement after HN_2 therapy. The fourth group is represented by three patients (Cases 4, 6, and 19) who did not improve following roentgen therapy and who also failed to improve after nitrogen mustard. Subsequent radiation, however, produced remissions in these patients. In the first three groups mentioned clinical remissions were observed following a total of twenty-four courses (55 per cent) and in twenty patients (65 per cent). In summary, a total of twenty-three patients received benefit from nitrogen mustard therapy either through an immediate remission or, indirectly, by an apparent re-establishment of sensitivity to roentgen rays. Since three of the thirty-one patients in this series (Cases 13, 26, and 27) did not return for follow-up studies after discharge from the hospital, the twenty-three who obtained benefit following HN_2 therapy represent 82 per cent of the twenty-eight cases in which subsequent clinical and laboratory observations could be made. Five patients (Cases 1, 15, 17, 21, and 28) were not benefited by HN_2 and subsequently expired.

In those patients in whom a remission was observed, the most troublesome symptoms of active Hodgkin's disease such as pain, pruritis, and occasional anorexia were relieved frequently after the third or fourth injection of the series. Fever was the most consistent clinical finding during exacerbations of Hodgkin's disease. In those cases in which a remission occurred, the temperature returned to normal during therapy or within a week after its completion. Many patients who noted no sustained subjective or objective evidence of regression of the disease nevertheless described a moderate degree of temporary relief from one or more of their symptoms. One patient (Case 14) developed a marked diffuse brown pigmentation of the skin during one exacerbation of the disease. Nitrogen mustard therapy was given and two weeks after completion of therapy the pigmentation had disappeared with the reappearance of a normal skin color. This decrease in abnormal skin pigmentation also was observed to a lesser degree in two other patients (Cases 2 and 9).

The toxic effects of the methyl-bis compound are fairly consistent. With the exception of one case in which diarrhea was present, anorexia, nausea, and vomiting were the only immediate toxic reactions. These symptoms occurred

during thirty eight of the forty four courses given and were usually apparent within one half to three hours following the administration of therapy. In some instances nausea alone of short duration was described. In others nausea and vomiting of twenty four to forty eight hours duration were noted. Thrombophlebitis at the site of injection occurred during four courses. This was an annoying though not a serious complication.

Following the administration of twenty three courses of nitrogen mustard therapy, thirteen patients developed maculopapular marbled pruritic skin lesions over the trunk and extremities. The lesions appeared from one to six weeks after treatment. Morphologically the eruption first appeared as pink, maculopapular lesions 2 to 5 mm in diameter. They later became hemorrhagic in some cases. Throughout the development of the eruption and during its course, pruritus was marked. The lesions usually persisted for many weeks but were relatively few in number. In some cases the eruption was scattered diffusely over the body, in others it was confined to one or more extremities or to a single area of the trunk. Grossly the lesions were similar to those which occasionally are seen as skin manifestations of Hodgkin's disease. Microscopically, however, biopsy material obtained from three patients studied was described as vesiculobullous lesions presumably resulting from vascular damage. The walls of the surrounding vessels showed marked degeneration. In addition to the maculopapular lesions described five of the thirty one patients in this series developed the classic lesions of herpes zoster.

The most serious complication following nitrogen mustard therapy in this series resulted from bone marrow and lymphoid tissue destruction. Blood studies considered adequate and suitable for hematologic evaluation were done following thirty five courses of therapy in twenty six patients. A leucopenia below 2000 white cells per cubic millimeter of blood was recorded following twenty two courses. In fifteen the white blood count dropped below 1000. The lymphocytes were the first cellular elements to reflect the toxic effect of the material. A decrease in the number of lymphocytes was observed as early as twenty four hours after the first dose of nitrogen mustard in some cases. Before the institution of HN₂ therapy an absolute lymphopenia (below twenty per cent) was apparent in all of the patients studied. Twenty five had less than 10 per cent and seventeen had less than 5 per cent lymphocytes before treatment. In the latter group (less than 5 per cent lymphocytes) a significant decrease in the number of circulating lymphocytes following therapy was obviously difficult to measure. Fourteen of the sixteen treatment courses given to patients whose blood contained more than 5 per cent lymphocytes before therapy demonstrated a significant drop in those cells within one to five days after the first dose was given. In twenty three of the thirty four courses subsequent blood studies revealed a return to the previous lymphocyte level or to a more nearly normal level. In nine courses three weeks after therapy 20 per cent of the circulating white blood cells were lymphocytes, a significant increase compared with the level before therapy. Four courses were followed by an immediate increase in lymphocytes. Two of these four experienced satisfactory remissions (Courses 17 and 42).

In addition to the lymphopenia present before therapy, in thirty-four of thirty-five instances an absolute monocytosis and an increased monocyte-lymphocyte ratio were found. The monocyte-lymphocyte ratio returned to normal and was accompanied by a satisfactory remission after fourteen of thirty-four courses. In eleven courses followed by no remission, the monocyte-lymphocyte ratio remained abnormal. When an alteration in the monocyte-lymphocyte ratio followed therapy, it consisted of both an increase in the total number of lymphocytes and a decrease in the number of monocytes. A direct correlation between variations in the monocyte-lymphocyte ratio and variation in the activity of the disease appeared to be present in twenty-five of thirty-four courses (74 per cent).

At the time when the leucopenia was most severe, approximately three weeks after therapy, all white blood cell elements were numerically reduced in equal proportion. Thrombocytopenia, when present, usually appeared a few days later than the leucopenia. A thrombocytopenia of less than 100,000 developed following seventeen of the thirty-four courses in which hematologic studies were made, thirteen patients had platelet counts below 50,000 and six below 10,000. Many of these patients developed petechiae, in one there was bleeding from the mucous membranes.

Twenty-four of the thirty-four treatment courses (71 per cent) followed hematologically demonstrated an increased reticulocyte count, as high as 10.8 per cent in one case, during exacerbations of the disease previous to nitrogen mustard therapy and during subsequent recrudescence of the disease. This reticulocytosis existed independent of the presence or absence of anemia. Following twenty-three of twenty-eight courses studied, the reticulocyte count dropped within two weeks following HN_2 therapy, to 0.0 in six instances, it remained above normal at its lowest point following nineteen courses (68 per cent). The most marked anemia was noted in most cases three to four weeks after HN_2 therapy and was recorded below 2.0 million red cells after eight of thirty-five treatment courses. The degree of anemia observed after therapy was dependent both on the red blood count before therapy and on the number of whole blood transfusions given the patient following therapy. A normal number of red blood cells present before treatment rarely was followed by a decrease of more than one to one and one-half million after nitrogen mustard. When the red blood cell level was low before therapy, a profound anemia frequently developed after HN_2 . Whole blood transfusions were adequate for maintenance preceding marrow regeneration.

Serial sternal marrow studies were made in ten cases. Three of these revealed increases in reticulum cells, monocytes, and plasma cells before therapy. In five cases a left shift in the erythroid series was seen before treatment but there was no significant quantitative alteration in any of the normal cell types. All ten marrow samples studied demonstrated a moderate to marked hypoplasia of all cellular elements after treatment with HN_2 . The diminution in marrow elements was apparent to some extent by the time therapy was completed five days after the first dose. Hypoplasia became more marked during

the subsequent two weeks and in most cases aplasia followed. Only fibroblasts and fat cells remained. After the period of aplasia, a normal regenerative process occurred with the appearance of young erythroid and myeloid forms in increasing numbers. Within five to six weeks after therapy, when the peripheral blood picture was approaching normal a hyperplasia and left shift of erythroid and myeloid elements and megakaryocytes were seen.

Serial blood sedimentation rates were determined following thirteen courses. A direct relation between clinical benefit and improvement in sedimentation rate was observed in eight of thirteen patients studied (62 per cent). The administration of folic acid in doses of 30 to 50 mg daily during and after approximately one half of the thirty-four courses observed did not seem to alter the cytotoxic effects of mustard therapy. Whole blood transfusions similarly did not alleviate the toxic depression of the marrow nor did they aid in maintaining a normal peripheral white blood cell or platelet level. All patients with a leucopenia below 2000 cells were given penicillin until the white blood count rose above this level. In three cases there was secondary infection directly associated with the granulocytopenia; the infection was controlled by penicillin in each case.

Both C E (Case 12) and G T (Case 14) whose histories are summarized below exhibited extensive damage of the hematopoietic system with return to a normal equilibrium in one and a partial return in the other. The latter patient (Case 14) experienced a longer and more complete remission than did the former (Case 12). However, in Courses 9, 12 and 14 (Cases 5, 7 and 9) illustrated in Table I, clinical remissions of two, five and two months respectively were observed in patients who had only minimal evidence of toxic damage to the blood and lymphoid systems.

CASE 12—C E, a 35 year old white woman entered University Hospital during March 1947 complaining of epigastric pain, weight loss, weakness and cough. The illness began during the third trimester of the patient's last pregnancy during the fall of 1944 when she noticed a swelling in the left side of the neck. A few weeks later the skin became yellow and pruritic. About three months after the uncomplicated full term delivery of a normal female child, the patient was referred to this clinic because of persisting cervical adenopathy. After a left supraclavicular lymph node biopsy in April 1945 the diagnosis of Hodgkin's disease was made. The patient then received roentgen therapy over the right and left cervical regions and the mediastinum. During the fall of 1945 she received further radiation over the axillae, mediastinum and epigastrium. She felt well until two months before remission when she developed epigastric pain which was more pronounced after eating. She stated that solid foods seemed "to get stuck" before reaching the stomach causing pain which lasted more than an hour. These symptoms progressed and were accompanied by cough, weakness, and weight loss.

Physical examination revealed a pale thin individual with cervical and axillary non-tender, firm, discrete nodes. Roentgen ray studies of the esophagus demonstrated an obstruction just behind the bifurcation of the trachea. A calcified inferior bifurcation node was visualized and roentgen ray findings suggested the possibility of ulceration into the esophagus. Following the administration of 25 mg of bis (β -chloroethyl) amine the patient became nauseated and vomited. Six days later roentgen ray examination revealed less evidence of obstruction and stenosis of the esophagus. For approximately two months the patient felt well and was able to eat solid foods without pain or difficulty. At that time dysphagia returned, became progressively more severe and was accompanied by cough.

Physical examination revealed a widening of the mediastinum to the right. A second course of 22.5 mg of nitrogen mustard was given. During the week after HN therapy the patient noticed her cough becoming more severe with swallowing and reported that she had coughed up food particles. A diagnosis of esophageal bronchial fistula was made and tubal suction via the esophagus was instituted. Fluoroscopic examination confirmed the diagnosis of fistula. The patient had a pruritic maculopapular eruption over the extremities and chest at this time.

FIG 1

In spite of whole blood transfusions, glucose infusions, and penicillin, the condition of the patient worsened and she expired on the twenty third hospital day, three months after the first course of nitrogen mustard. The skin eruption became more extensive and severe about one week after the second course of mustard therapy. The anatomic findings at autopsy were (1) Bronchoesophageal fistula, (2) necrotic ulceration of the esophagus, (3) mediastinal lymphadenitis, (4) pulmonary infarction and emphysema, (5) fibrinous pleuritis, (6) multiple gastric ulcers with mucosal hemorrhage. The hematologic findings in this case are illustrated in Fig 1.

CASE 14—G T, a 16 year old white girl, was admitted to the University Hospital February, 1947, complaining of weakness, enlarged glands, itching of the skin, and cough. In 1944 the patient noticed increasing weakness, easy fatigability, and enlarged left cervical

nodes. A diagnosis of Hodgkin's disease was made following study of a lymph node biopsy section and the patient was referred to this clinic. Following biopsy the patient received multiple courses of roentgen therapy over the mediastinum, lung, abdomen and cervical and inguinal region. The patient noted no peripheral edema during subsequent exacerbations but returned for roentgen treatment repeatedly because of recurrence of the weakness and weight loss. Six months before admission for HN therapy the patient had severe generalized pruritis which continued until admission. One month before admission she developed a cough productive of thick yellow white sputum. Pain in the substernal region accompanied the cough. On admission fever, night sweat, occasional chill, productive cough, and weakness were described.

File

Emaciation, dark brown pigmentation of the skin and a papular eruption over the entire body with excoriations were present. There was no significant adenopathy. Roentgen ray studies revealed a right pleural effusion with apparent involvement of the right upper lobe lung parenchyma by Hodgkin's process.

The patient received five daily doses of bis (β chloroethyl) amino hydrochloride (50 mg) with no untoward reaction. Ten days after the first dose roentgen studies revealed a diminution in the pleural effusion and increased aeration in the right lung apex. The temperature 10. to 10.5 before therapy was observed to be 105 on the first day of therapy. Two days after the first dose of nitrovin mustard the temperature was 100 and varied

between 98.0 and 101 until seventeen days after the beginning of therapy at which time it returned to normal. The hematologic changes are illustrated in Fig. 2. The patient received 30,000 units of penicillin every three hours from the second day of treatment until discharge and 50 mg. folic acid orally every day after the twelfth day following the first dose of nitrogen mustard. She received four transfusions of 50 c.c. of whole blood during the second week after treatment. Pruritis and the papular eruption became less noticeable and were absent when the patient was discharged twenty-four days after the beginning of treatment. At the time of discharge the brown skin pigmentation had almost disappeared. Appetite, sleep, and general well-being were improved. The severity of the cough had greatly decreased and only a small amount of thin clear sputum was obtained. Two weeks after discharge the patient returned feeling well except for a recurrence of the skin eruption with pruritis accompanied by lesions similar to those of herpes zoster. Although the herpetiform lesions disappeared in three to four weeks, the papular pruritic eruption persisted intermittently until a second course of nitrogen mustard was given six months later following a recurrence of fever and a progression of the pulmonary lesions.

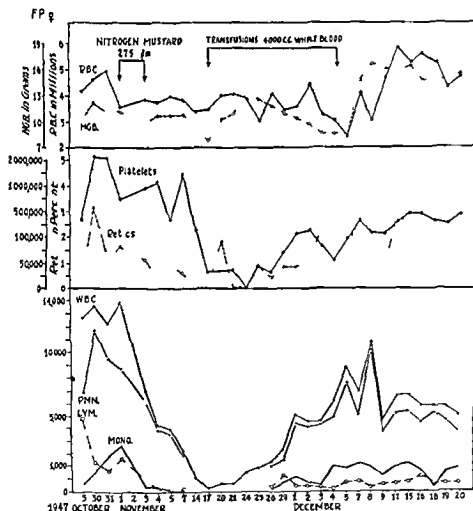

Fig. 5

CASE 31—F P a 29-year-old white married woman was first diagnosed as having chronic lymphatic leucemia on the basis of a supraclavicular lymph node biopsy nine years before admission. For five years she received roentgen therapy over multiple areas of recurrent adenopathy. During most of that time she was able to maintain normal activity. Four years before admission to the hospital a second lymph node biopsy gave a diagnosis of Hodgkin's disease and this diagnosis was reinforced by a review of the old slides. Since then the patient had continued to receive occasional roentgen ray treatments. During the six months preceding this admission she noted progressive weakness, dry cough, intermittent afternoon fever, substernal chest pain, and pain over the right inferior angle of the scapula. Roentgen ray studies revealed an enlargement of the mediastinal shadow which was inter-

pieted as being due to adenopathy. The patient was given a total of 1,200 roentgens in over each of three fields: anterior and posterior mediastinum, and right lateral chest. The latter therapy did not bring about relief of symptoms. On admission to the hospital the patient also had complained of a sense of fullness in the epigastrium and pain in the right upper quadrant for minutes to hours following the ingestion of any type of food.

Roentgen ray studies of the gastrointestinal tract, gall bladder, and kidneys demonstrated a distortion suggesting adenopathy in the right lumbar and celiac axis nodes. The gall bladder could not be visualized. Basal metabolic rate on admission was plus 3 per cent, blood urea nitrogen was 11.5. Prothrombin was 86.5 per cent, brom-sulfaleum, 10 per cent in both specimens, direct van den Bergh, 0.2, indirect, 0.75. Total protein was 6.0, albumin 3.75, and globulin 3.00. The serial hematologic studies are illustrated in Fig. 5.

The patient was given two doses of methyl bis (β -chloroethyl) amine hydrochloride of 110 mg. on two successive days and 55 mg. on the third day. The patient experienced nausea and vomiting during and for one day after the course of therapy. The pain disappeared during the first week after treatment. A cholecystogram ten days after the first dose revealed a normally functioning gall bladder. The patient was discharged eleven days after the first dose of HN, apparently improved in every respect.

Six days after discharge the patient was readmitted, having felt well until three days after discharge. At this time she experienced fever, chills, malaise, nausea, and vomiting. Physical examination revealed an ulceration of the gingiva and petechiae on the soft palate. The abdomen was diffusely tender. The oral temperature was 102° F. The white blood count was 150 and the red blood count was 3.36 million, no platelets or reticulocytes were seen. The sternal marrow was aplastic, only fibroblasts, fat and plasma cells were found. The prothrombin was 44 per cent of normal, total protein 6.00 Gm. per cent, albumin 3.42 Gm. per cent, globulin 2.58 Gm. per cent. There was 40 mg. per cent albuminuria and a blood urea nitrogen of 31.5.

The patient was given 50,000 units of penicillin every three hours but continued to have a septic temperature. No new physical signs developed until five days after admission when a rapidly progressive jaundice appeared. At this time the van den Bergh was indirect 13.2, direct 10.35, cephalin was 1 plus, total protein 6.75, albumin 2.37, and globulin 3.38. Thrombocytopenia was 20. During the course of this admission 3,500 cc. of whole blood were given without untoward reaction. Streptomycin (4 Gm. daily) was started on the fourth hospital day. The patient became distended on the seventh hospital day and a Miller Abbott tube was inserted. On the following day a right lower lobe pneumonia and atelectasis became manifest. Ten days after admission a mass was palpated in the right lower quadrant. A barium enema demonstrated a perforation of the posterior aspect of the cecum with escape of the barium into the retroperitoneal space. An incision and drainage of the retrocecal retroperitoneal abscess were done. The temperature returned to normal within three days after surgery and the patient began to improve. *Escherichia coli* and staphylococci were obtained on culture of the abscess fluid.

The van den Bergh, blood protein, prothrombin, and lung findings returned to normal within one month after the abscess drainage and at that time the drainage tube was removed. Priodax roentgen ray studies revealed closure of the abscess cavity. The cecal perforation could not be demonstrated two weeks after surgical intervention.

DISCUSSION

Remissions of one to ten months have been observed following HN therapy in the series of cases presented in this report. There appear to be several types of patient who may obtain benefit from this form of therapy. First, nitrovin mustard has produced remissions in the clinical course both of patients who had never been given roentgen therapy and in patients who had previously received beneficial effects from roentgen radiation. Second, HN has been used

successfully in individuals who had widely disseminated Hodgkin's disease with severe systemic intoxication who were therefore unsuitable subjects for radiation therapy. Third, a regression of the disease after nitrogen mustard therapy has been observed in cases in which recent roentgen treatment over involved areas failed to produce beneficial results. Finally, an indirect benefit apparently was obtained in selected patients who previously had been considered roentgen ray resistant and who demonstrated no apparent improvement after nitrogen mustard therapy. In these patients an apparent resensitization to roentgen rays was established.

One of the most consistent clinical signs of an exacerbation of Hodgkin's disease in the present series was the presence of fever either Pel Ebsen or septic in type. As exemplified by G. T., Case 14 a decrease in temperature during or within a few days after therapy was observed sufficiently often to justify the use of this observation as an early index of the efficacy of the treatment. Relief of pain, observed in patients G. T. and F. P. (Cases 14 and 31) was also an early manifestation of a remission. Viciously pruritic skin lesions an annoying counterpart of many cases of Hodgkin's disease disappeared shortly after HN therapy in G. T. (Case 14). Objective signs of a clinical remission are exemplified by the case report of G. T. In the presence of extensive pulmonary involvement HN therapy was followed by increased aeration of the lung, a diminished amount of sputum and a decreased cough. Another objective change was observed in F. P. (Case 31) in whom the gall bladder, nonfunctioning before treatment was reported to be normal after HN therapy. The symptoms suggestive of gall bladder disease before therapy also disappeared. Skin pigmentation, a sign occasionally encountered in Hodgkin's disease disappeared within a few days after HN therapy in a few cases (Case 14). In Cases 14 and 31 a regression of the disease process was demonstrated in organs other than those usually associated with the lymphoid system. The toxic reactions to the nitrogen mustard therapy were fairly consistent for example, nausea and vomiting occurred as an immediate toxic effect following each dose of HN in 78 per cent of the courses given. The thrombophlebitis observed at the site of intravenous injection of this medication was an annoying but minor complication. The causal factor in the development of skin lesions in a number of patients after HN therapy remains to be determined. It cannot be stated whether this was a cutaneous spread of Hodgkin's disease after nitrogen mustard or a toxic effect resulting from local or systemic vascular damage. The profound leucopenia and thrombocytopenia observed after HN therapy reflects the extensive toxic damage to the hemtopoietic system. The fact that the lymphocytes were the first cellular elements to be decreased in the peripheral blood suggests that the lymphocyte is the most rapidly destroyed of the formed elements of the blood. That the destruction of blood cell elements occurs as a result of a central toxic effect as well as a peripheral one is demonstrated by the concomitant destructive hypoplasia and aplasia of the bone marrow observed during the period when the peripheral count is lowest. The appearance of hyperplasia of the bone marrow and increased numbers of young

forms of myeloid and erythroid elements as well as megakaryocytes while the peripheral cellular elements are increasing during the recovery phase indicates the duration and the temporary nature of this toxic effect on the blood cell forming precursors of the hematopoietic system.

The most consistent hematologic abnormalities in Hodgkin's disease before therapy are lymphopenia, monocytosis, and reversed monocyte-lymphocyte ratio. The subsequent regeneration of the lymphoid tissues and return to normal of the circulating lymphocytes after therapy reestablishes a more nearly normal monocyte-lymphocyte ratio. In this series of patients the return of the monocyte-lymphocyte ratio toward normal was the most consistent laboratory finding associated with a clinical remission.

An exacerbation of Hodgkin's disease in these cases was also reflected to some extent by an absolute reticulocytosis before therapy regardless of the presence or absence of anemia. The alterations in the reticulocyte count accompanying the bone marrow changes after HN_2 therapy prohibit its use as a prognostic index of the results of treatment.

In considering patients for nitrogen mustard therapy, it should be noted that the danger of the toxic effect of HN_2 on the bone marrow is minimized by two factors. One of these is the ability of antibacterial chemotherapeutic agents to alleviate the danger of infection resulting from temporary agranulocytosis and the other is the tremendous capacity of hematopoietic tissue to regenerate despite extensive damage by HN_2 . Similarly, evidences of bone marrow involvement by Hodgkin's disease before therapy with accompanying anemia, leucopenia, and thrombocytopenia do not constitute an absolute contraindication to HN_2 .

The fact that no consistent relationship was observed in some cases following nitrogen mustard therapy between the appearance of a clinical remission and the amount of hematopoietic and lymphoid tissue damage as measured by peripheral blood and sternal marrow changes indicates that hematopoietic tissue damage is not necessarily a criterion of the benefit to the patient resulting from this treatment. Two patients (Cases 11 and 29) in whom a satisfactory regression of the disease was observed not only failed to present gross evidence of hematopoietic damage on study of the peripheral blood but actually were observed to have an immediate increase in circulating lymphocytes following therapy.

The case reports presented described some unusual complications which might be considered as toxic reactions following treatment because of their occurrence shortly after nitrogen mustard therapy. Treatment with HN_2 was followed in one case by a perforation of the esophagus and esophageal and gastric mucosal ulcerations, and in another by a cecal perforation, gastric and duodenal ulcers were observed in a third. One patient developed marked jaundice and evidences of severe liver damage shortly after treatment, findings which returned to normal a few weeks later. It cannot be determined whether any or all of these changes are the direct result of the action of nitrogen mustard or are a secondary manifestation of the destruction of active Hodgkin-

tissue. If the former is true, the destructive effect on the gastrointestinal mucosa of experimental animals by toxic doses of nitrogen mustards may also be observed in some cases at therapeutic dose levels in human beings.

Nitrogen mustard appears to be a valuable adjunct to the therapy of Hodgkin's disease although it does not replace roentgen therapy. A comparison of previously recorded results following roentgen radiation with those following the selective use of both roentgen radiation and nitrogen mustard therapy suggests that the combination of therapeutic agents may offer greater hope for increased life expectancy than either used alone.

SUMMARY

Thirty-one cases of Hodgkin's disease were treated with a total of forty-four courses of methyl bis (β -chloroethyl) amine hydrochloride.

Beneficial results were observed in twenty patients receiving twenty-four courses. Indirectly, three other patients benefited through an apparent resensitization to roentgen rays. Improvement was characterized in most instances by an immediate disappearance of fever, itching and pain. Brownish pigmentation of the skin was observed to decrease in several cases as did Hodgkin's skin lesions, splenomegaly, hepatomegaly, and adenopathy.

The toxic effects of HN on hematopoietic and lymphoid tissues as reflected in peripheral blood and sternal marrow changes are described and discussed. These changes are contrasted with alterations in hematologic equilibria observed during exacerbations of Hodgkin's disease. Lymphopenia with a reversed monocyte-lymphocyte ratio is frequently observed during the active phase of Hodgkin's disease. A regeneration of lymphocytes and return of the monocyte-lymphocyte ratio toward normal is the most consistent laboratory finding associated with a clinical remission. An absolute reticulocytosis has been observed in many cases during the active phase of Hodgkin's disease before therapy regardless of the presence or absence of anemia. It is observed that no apparent relationship exists in selected cases between the amount of measurable damage to the hematopoietic and lymphoid tissues and the occurrence of clinical remissions. Bone marrow hypoplasia proceeding to aplasia and followed in every instance by complete regeneration to the previous level and in some cases to a more normal level within a few weeks after therapy was observed. Bone marrow involvement by the Hodgkin's disease process before therapy is not considered a contraindication to HN therapy.

An immediate toxic reaction of nausea and vomiting was observed consistently after HN therapy. Case reports have been presented describing unusual complications which followed HN therapy. These include ulceration and perforation of the mucosa of the gastrointestinal tract. Skin lesions macroscopically similar to those frequently seen in Hodgkin's disease appeared in an unusually large number of cases following HN therapy.

THE EFFECT OF LIVER EXTRACT AND VITAMIN B₁₂ ON THE MUCOUS MEMBRANE LESIONS OF MACROCYTIC ANEMIA

ROBERT E. STONE, M.D. AND TOM D. SPIES, M.D.
BIRMINGHAM, ALA.

FOR more than twenty years we have been studying the mucous membrane lesions of persons with macrocytic anemia and have observed that they usually are relieved by liver extract and Ventriculin. A great opportunity to study more carefully the pathogenesis of these lesions appeared with the advent of pteroylglutamic acid (folic acid) in 1945¹ and 5-methyl methyl (thymine) in 1946² two pure chemical compounds which are effective in producing a hematologic response in certain types of macrocytic anemia.

As soon as it had been demonstrated³ that synthetic folic acid and synthetic thymine were effective in producing a hemopoietic and clinical response in persons with pernicious anemia and related anemias,⁴ additional studies on these substances were planned. These studies were directed toward answering the following questions: What clinical syndromes are affected by these chemical compounds? What is the relation of the structure of the molecule of these compounds to their antianemic properties? What are the relative clinical and hematologic effects of these substances as contrasted with each other and as contrasted with liver extract? How well do these substances maintain patients with pernicious anemia, nutritional macrocytic anemia and tropical sprue? As a partial answer to this last query we (and many others) during the past two and one half years have found that folic acid maintains the blood levels in persons with pernicious anemia just as well as liver extract but that it does not offer a complete treatment in most cases since it does not prevent or relieve subacute combined degeneration of the spinal cord.⁵ It appears from our studies that folic acid is preferable to liver extract in the maintenance of persons with nutritional macrocytic anemia and tropical sprue.⁶ We have found that thymine, like folic acid, is not a complete treatment in most cases of pernicious anemia since it neither prevents nor relieves the subacute combined degeneration of the spinal cord although it does maintain the blood levels very well.⁸ Unpublished observations show that massive doses of thymine are as effective as liver extract or folic acid both clinically and hematologically in maintaining persons with nutritional macrocytic anemia and tropical sprue. The very large dose required, however, makes thymine impractical as a therapeutic agent.

From the Department of Nutrition and Metabolism, Northwestern University, Chicago, Ill.; Northwestern University Studies in Nutrition and Metabolism at the Hillman Hospital, Birmingham, Ala.

This study was aided by grants from E.R. Lilly & Company, Indianapolis, Ind., and Lederle Laboratories, Inc., New York, N. Y.

The folic acid was furnished by Dr. Stanton M. Hardy of Lederle Laboratories, Inc.; the thymine by Dr. J. A. Lechmann of Hoffmann-La Roche, Inc., Nutley, N. J.; and the human B₁₂ by Dr. Augustus Gibson of Merck and Company, Inc., Rahway, N. J.

Received for publication May 24, 1948.

At the Nutrition Clinic, Hillman Hospital, Birmingham, Ala.; at the Cillato Garcia Hospital, Havana, Cuba; and at the School of Tropical Medicine, San Juan, Puerto Rico.

In our two and one-half years of study, the administration of either folic acid or thymine did not result in healing the very severe mucous membrane lesions in cases of pernicious anemia. In every instance the administration of liver extract was followed by prompt improvement. This improvement lasted for varying degrees of time after the cessation of liver extract therapy. The earliest relapse occurred one month after therapy was discontinued, and several patients had had no recurrences twelve months after therapy was discontinued. The great majority had a recurrence from within one to nine months after the last injection.

Three of the patients were uncooperative and, feeling very much better, would return to work and not wish treatment again. When they relapsed they returned to us. These three patients had, at intervals, treatment with massive doses of thymine, parenteral liver extract, and oral administration of folic acid. In addition two of them had treatment with vitamin B₁₂, the newest vitamin to be isolated^{9, 10} and found to be effective in producing a clinical and hematologic response in persons with Addisonian pernicious anemia, nutritional macrocytic anemia, and tropical sprue¹¹⁻¹³. The fiery redness and intense pain of the mucous membrane lesions were relieved at least temporarily, in these two patients. A case history which is representative of the patients with severe lesions follows.

J. B., a 48 year old white man. A diagnosis of pernicious anemia was first made in May, 1944. At that time he complained of general weakness, dyspnea and palpitation on exertion, soreness of mouth and tongue, swelling of feet and legs, and paresthesias of the extremities. The tongue was smooth (severe atrophy of papillae) and red, the gums were swollen and injected, and scars were present at the angles of the mouth. Sensory changes suggestive of peripheral neuritis were noted. The initial blood values were: red blood cell count, 1.25 million, hemoglobin, 5.1 Gm (33 per cent), reticulocytes, 18 per cent, white blood cell count, 3,250, packed cell volume, 16, mean corpuscular volume, 128, mean corpuscular hemoglobin, 40.8, and mean corpuscular hemoglobin concentration, 31.8. Many megaloblasts were present in the aspirated sternal marrow. Other pertinent laboratory data were: achlorhydria and achylia after histamine stimulation, slightly elevated icteric index, and negative gastrointestinal x-ray studies. Therapy with a small amount of an experimental liver fraction resulted in partial relief clinically and hematologically.

Within a period of six months the anemia and associated symptoms relapsed. The symptoms and physical findings were essentially the same as noted on the first occasion. The blood counts were: red blood cells, 1.39 million, hemoglobin 4.4 Gm, and reticulocytes 42 per cent. Therapy with commercial liver extract (Reticulogen) induced a remission rapidly. A peak reticulocyte count of 37.3 per cent was obtained on the sixth day of therapy. Five to seven days after therapy was started the red blood cell count was 5.08 million and hemoglobin was 13.1 grams. Clinical improvement was just as remarkable. The signs and symptoms of glossitis and stomatitis subsided rapidly, and regrowth of lingual papillae was observed.

After an interval of nine months without therapy the patient was observed a third time in severe relapse in September, 1945. In addition to the symptoms and physical signs of anemia per se, there were severe glossitis and stomatitis and moderately severe paresthesias and physical signs of peripheral neuritis. The initial red blood cell count was 1.04 million and hemoglobin was 7.1 grams. The patient was given 100 mg of folic acid daily in mouth for twenty days. A peak reticulocyte count of 19.2 per cent was obtained on the fifth day of therapy. Sixty-five days after folic acid was started the red blood cell count was 4.97 million and hemoglobin was 12.5 grams. Symptoms and physical signs of glossitis and stomatitis subsided entirely within ten days, and on the patient's release from the hospital the neurological examination was negative.

A fourth relapse developed within five months after the folic acid therapy was discontinued. The symptoms and physical findings in March, 1946 were essentially the same as noted on the three previous occasions except that there was evidence of progression of the peripheral neuritis. The blood counts were: red blood cells, 1.55 million, hemoglobin 6.2 Gm (40 per cent), white blood cells 3,050, reticulocytes 0.3 per cent, packed cell volume 20, mean corpuscular volume, 129, mean corpuscular hemoglobin 40 and mean corpuscular hemoglobin concentration 31. Therapy consisted of 5 methyl uracil (thymine) 6 Gm daily by mouth for nineteen days. A peak reticulocyte count of 16 per cent was obtained on the eleventh day of therapy. Twenty-one days after therapy was started the red blood cell count was 2.39 million and hemoglobin was 8.9 Gm, an increase of about one half million red blood cells and 3.1 Gm of hemoglobin in three weeks time. Although studies of sternal marrow which was aspirated just after the peak of reticulocytosis revealed a normoblastic reactive stage comparable to that observed during therapy with liver extract and on another occasion with folic acid the anemia began to relapse soon after therapy was discontinued. Neither the stomatitis and glossitis nor the nervous symptoms were relieved. While the patient was taking thymine the glossitis and stomatitis became worse with swelling and increased burning soreness of mouth and tongue and ulceration and fissuring of mucosa of lower lip.

The patient left the hospital against advice, thus interrupting therapy. However on June 29, 1946, he returned to the clinic and was started on folic acid 10 mg daily by mouth. At that time symptoms and signs of glossitis and stomatitis were still present. The patient received the folic acid (10 mg four times a day) for thirteen days. A peak reticulocyte count of 26.6 per cent was obtained on the eleventh day of therapy. During the twenty-three days he was observed, the red blood cell count increased from 0.91 million to 2.19 million, and hemoglobin from 4.0 to 7.9 grams. Throughout that period glossitis and stomatitis persisted. The patient insisted on leaving the hospital again.

He was readmitted to the hospital in September 1946. Despite the persistence of severe anemia and glossitis and stomatitis he had worked regularly at a cotton mill during the previous sixty days. During that time however paresthesias recurred and became progressively worse, and disturbed locomotion developed. The patient was given liver extract intramuscularly and improved gradually both clinically and hematologically. On December 18, 1946 the red blood cell count was 4.60 million and hemoglobin was 12.7 grams. The patient refused more therapy and returned to work.

During June 1947, the patient had an insidious onset of soreness, stinging and burning sensation of the mouth and tongue, progressive general weakness and dyspnea on exertion, and mild paresthesias of extremities. Six weeks later in July 1947 when he returned to the outpatient clinic a moderately severe glossitis and stomatitis, anemia, chronic peripheral neuritis and possibly posterior column degeneration were found. Blood counts were: red blood cells 2.00 million, hemoglobin 9.0 Gm (52 per cent), reticulocytes 0.3 per cent, white blood cells 3,200, packed cell volume, 20, mean corpuscular volume 130, mean corpuscular hemoglobin 40 and mean corpuscular hemoglobin concentration 31. A single dose 1 cc of a highly refined commercial liver extract was given intramuscularly. During the subsequent ten days the stomatitis, glossitis and cheilosis cleared rapidly and regeneration of lingual papillae began. The anemia likewise improved; the blood values obtained four weeks later were: red blood cell count 3.86 million, hemoglobin 12.2 Gm (79 per cent), reticulocytes, 0.4 per cent and white blood cell count 6,550. The patient again refused more treatment and returned to work.

During October, however, there was a gradual return of all symptoms which by the time of admission to the hospital a month later had become severe. The patient's tongue was swollen, deep dental impressions were present at the tip, all surfaces were red and the papillae apparently were severely atrophied; the buccal mucosa appeared slightly swollen and large areas were hyperemic, particularly opposite the line of closure of the teeth; tooth indentations marked the mucosa of the lower lip and several oozing fissure extended laterally externally from the left angle of the mouth.

Folic acid, 10 mg daily by mouth was started on Dec 14, 1947 and continued on March 3, 1948—a total of eighty days. It was then increased to 40 mg a day for thirty

four days, and finally to 50 mg a day for an additional period of twenty two days. At the dose of folic acid was increased to 50 mg a day, the patient received simultaneously 600 mg of niacinamide a day for seven days. Then during the next fifteen days the following vitamins (in addition to folic acid), with daily doses as indicated, were given: Vitamin A, 75,000 U.S.P. units, vitamin D, 3,000 U.S.P. units, thiamine 30 mg, riboflavin, 10 mg, niacinamide, 450 mg, ascorbic acid, 450 milligrams. While the patient was on this therapy there was considerable, but suboptimal, improvement of the anemias, but no appreciable beneficial effect, either from the folic acid alone or from the other vitamins, on the glossitis, stomatitis, and cheilosis resulted. The blood values at the beginning of therapy were: red blood cell count, 2.15 million, hemoglobin, 8.1 Gm (53 per cent), reticulocytes, 0.6 per cent, and white blood cell count, 4,900. At the conclusion of therapy (a total of 104 days) they were: red blood cell count, 4.15 million, hemoglobin, 14.2 Gm (92 per cent), reticulocytes, 2.2 per cent, and white blood cell count, 9,250. A peak reticulocyte count of 18.1 per cent was obtained on the eleventh day of folic acid therapy (10 mg four times a day).

Despite the fact that the patient's blood values were as high as we had ever seen them, the stomatitis and glossitis were worse. The fiery redness was more intense. The pain made it almost unbearable, so on April 30, 15 μ g of vitamin B₁₂ were given intramuscularly. Within twenty four hours there were equivocal signs of improvement. After forty eight hours there was definite fading of the hyperemia of the tongue and buccal mucosa. By the fifth day after the injection, the color of the mucosa of the tongue and oral cavity appeared about normal except in the most swollen areas of the lower lip, at this time the external nares were dry and appeared to be healing. The tongue appeared less swollen, and by the thirteenth day many fine papillae were visible over the entire upper surface and the external fissures appeared completely healed. All soreness and burning sensation of the mouth, tongue, and external fissures began to subside within forty eight hours after the injection and completely disappeared within five days.

SUMMARY AND CONCLUSIONS

These studies show that certain patients with Addisonian pernicious anemia have severe mucous membrane lesions that are not relieved by the administration of massive doses of thymine or large doses of folic acid. These severe mucous membrane lesions are characterized by a fiery red appearance and, in most instances, excruciating pain to the patients. These severe lesions have been seen only in patients with pernicious anemia, that is to say, patients who had gastric achlorhydria and achylia, and in each instance these lesions have occurred only in people who had subacute combined degeneration of the spinal cord. There seems to be a close clinical association between the gastric defect, the severe mucous membrane lesions, and the degeneration of the posterior and lateral columns of the spinal cord in these particular patients.

Without exception, the patients in our experience, as illustrated by the case history, have benefited from liver extract injections, and two of them were given vitamin B₁₂ with similar relief for at least two weeks' time. These findings support our previous contention that neither thymine nor folic acid is a complete treatment for persons with pernicious anemia, whereas, in contrast, parenteral liver extract is.

THE EFFECT OF 2, 3-DITHIOPROPANOL (BAL) ON GOLD TOXICITY IN RATS

C S GILLMOR, M.D.,* KANSAS CITY, Mo, AND
R H FREYBERG, M.D., NEW YORK, N Y

GOLD salts have been used in the treatment of rheumatoid arthritis since they were introduced by Forestier¹ in 1929. Toxicity sometimes occurring with the use of gold salts has been an important factor limiting the more general use of this form of therapy.

Treatment of toxicity due to gold for the most part has been unsuccessful. 2,3-Dithiopropanol (BAL) has been reported² by a group of investigators to be successful in counteracting arsenic and mercury poisoning. These investigators made no report on the effect of BAL against gold toxicity.

Because of the value of BAL in the treatment of intoxication from other heavy metals, it seemed appropriate to study the effect of BAL in the prevention and treatment of toxicity due to gold. Clinical investigations will be reviewed separately, it is the purpose of this paper to report the effect of BAL in prophylaxis and therapy of the experimental gold toxicity in albino rats.

EXPERIMENTAL

Albino rats averaging 160 grams in weight were used as experimental animals. Gold sodium thiosulfate, $\text{Na}_2\text{Au}(\text{S}_2\text{O}_3)_2$, in a 37½ per cent aqueous solution was the gold salt used in every instance. BAL always was injected in doses of 0.0375 c.c., which is ten times the average dose recommended for the treatment of acute arsenic or mercury poisoning in human beings†. All injections of gold salt and BAL were made intramuscularly. The experimental animals were divided into three groups of twelve. Each of the rats in Group A was injected daily for seven days with an amount of gold sodium thiosulfate containing 18 mg. of gold. An injection of BAL was made into six rats of this group on the fifth and sixth experimental days. Each rat in Group B received 47 mg. of gold daily for four days. On the third and fourth experimental days, BAL was injected twice daily into half of the animals in this group. Each rat in Group C received 38 mg. of gold daily for seven days. BAL was injected into six of these animals twice daily on the first three days of the experiment and once daily on the fourth through the seventh day. At the end of each experiment the animals were killed and the organs were carefully examined.

RESULTS

All rats in Group A showed no change in general appearance, but they were less active and had diminished appetites. In behavior no differences were noted between the animals which received BAL and those that did not. One rat in the control group died on the third day, all others were killed on the seventh experimental day. Sections of the kidneys of the rats treated with BAL, in

‡The distributors of BAL (Hynson, Westcott & Dunning, Inc., Baltimore, Md.) recommend injections of 25 mg. per kilogram body weight to be given several times daily for several days.

TABLE I CONDENSED RESULTS OF EXPERIMENT

RATS	GOLD INJECTED	BAL INJECTED	KIDNEY PATHOLOGY	REMARKS
Group A (1) 6	18 mg daily for 7 days	0.0375 cc twice daily for 2 days starting on fifth day	Moderate tubular degeneration with deposits of gold in tubules	Movements moderately slowed rats killed on seventh day of experiment
(2) 6 (control)	18 mg daily for 7 days	None	Same	Same
Group B (1) 6	47 mg daily for 4 days	0.0375 cc twice daily for 2 days starting on third day	Severe tubular degeneration extensive deposit of gold in tubules	Four rats died of toxic effects of gold before BAL was administered two rats from B transferred to B as substitutes four rats died at end of third day all rats were listless had poor appetites ruffled fur and pale eyes and tails
(2) 6 (control)	47 mg daily for 4 days	None	Same	Four remaining control rats were listless had poor appetite and pale eyes and tails rats killed at end of fourth day
Group C (1) 6	38 mg daily for 7 days	Starting on first day 0.037 cc twice daily for 3 days then once daily for 4 days	Only moderate tubular degeneration no deposits of gold salts in tubules	Rats appeared well good appetite normal fur no pallor animals killed on twenty second day for examination
(2) 6 (control)	38 mg daily for 7 days	None	Severe tubular degeneration with deposits of gold in tubules	Rats listless inactive had poor appetite and were pale from second day, two rats died on second day, 2 on third day and 1 on fifth day remaining rat killed on eighth day for examination

Group A, revealed quite normal glomeruli most tubules appeared to be entirely normal. Some tubular cells showed a moderate degree of granular degeneration in the lumina of these tubules there was frequently an albuminous precipitate. The most striking abnormality was the pigmented precipitate found in tubular cells. Dark orange and fine, red granules were seen in the epithelium of many convoluted tubules. There were some scattered deposits of golden yellow granules but these were relatively scant as compared with the fine orange red deposits. Marked congestion of the interlobular vessels was present. The collective tubules were normal, but moderate congestion of the medullary capillaries was present. The kidneys of the control rats of Group A (those animals that received no BAL) showed the same changes in the same degree as were found in the rats treated with BAL (Table I).

Of Group B, four rats died before BAL was started on the third day. The experiment was continued with four rats receiving gold and BAL and four rats served as controls. When BAL was started the entire group were listless had ruffled fur did not eat and had little color in ears and tails. The rats injected with BAL died within ninety six hours and the rats in the control group were killed on the fourth day.

In the kidneys of all animals in Group B there was severe degeneration of the epithelium in the convoluted tubules, in a patchy distribution in the epithelium and lumen. In the kidneys of rats that received no BAL, many convoluted tubules contained clumps of golden yellow granular pigment of various sizes. This pigment was found both in the epithelium and in the lumen. Some of the epithelium was necrotic and was fused to form a pale, granular, homogeneous coagulum filling and sometimes blocking the lumen. Numerous eosinophilic casts were present in the collecting tubules and in the loops of Henle. Deeply stained eosin casts blocked some collecting tubules. Among those rats that were not injected with BAL, the collecting tubules of the kidneys contained pigment also, this was usually in small, light-golden granules.

In Group C, the six rats receiving gold and BAL simultaneously appeared to be entirely normal, they ate well and were normally active during the whole experiment. They were killed on the twenty-second day in order to examine the kidneys. The control rats (which received no BAL) were listless and inactive from the second experimental day onward. Two rats of this group died at the end of the second day, two died on the third day, and one rat died on the fifth day of the experiment. The one remaining rat of this group was killed on the eighth day.

Examination of the kidneys of rats from Group C showed interesting changes. A kidney from the rat which received no BAL weighed 1.55 grams, as contrasted to 1.0 gram, the average weight of one kidney from rats in this group which were injected with BAL. In the kidneys of the rats that received gold and BAL there was only moderate degeneration of epithelium in the convoluted tubules. Some of the tubules contained a small amount of albumin and occasional casts. No metallic precipitate was observed in the tissue. The kidneys of the rats in Group C that received no BAL showed severe degenerative changes, necrosis, and gold precipitate in abundance exactly as seen in the rats of Group B that received no BAL.

In none of the experimental animals was there any evidence of abscess formation in the muscle into which injections of BAL or of gold sodium thiosulfate were made.

DISCUSSION

In order to be certain that the abnormalities seen in the kidneys of the experimental animals were produced by the gold sodium thiosulfate injected, the kidneys of two normal, untreated rats were carefully examined. They contained no orange-red or golden yellow precipitate. Parenchymatous elements were well preserved. Some tubules showed slight vacuolar degeneration of the epithelium, and occasional hyaline casts were seen. There was considerable congestion of the glomerular and interstitial capillaries. The pigment precipitated in the kidney tissue and the renal cellular damage observed in the rats of this investigation were exactly like the changes due to gold toxicity produced in earlier studies conducted by one of us.⁴

In these investigations the toxicity of gold was similar to that previously described in white rats.⁴ The chief pathologic change was in the kidneys where

nephrosis similar to that caused by some other heavy metals resulted. When the dose of gold is sufficiently large death may result quickly as was the case in the animals in Group B. Because of this the dose of gold was reduced in the studies conducted on the animals of Group C to permit sufficient time for any beneficial effects of BAL to be accomplished.

It is clear from these studies that even in large doses BAL had no therapeutic value when it was injected after extensive cellular damage already had occurred. When given simultaneously with large doses of gold sufficient to cause death in many animals of Group C BAL proved to be effective in combating toxicity from gold. Even though some renal damage then occurred it was of small amount and insufficient to cause systemic toxicity in the rats which lived and appeared well until they were killed in order to examine the tissues.

Besides the definite decrease in cellular damage a conspicuous difference in appearance of the kidneys of the rats in Group C which were treated with BAL was that no precipitate of gold or gold salt was observed in the convoluted tubules. This observation suggests that BAL combines with the gold instead of the tissue cells and keeps it in the body in a nontoxic state or eliminates it as such so as to prevent any significant cellular damage or its precipitation in renal tissue. It appears that BAL successfully competes with the host tissues for combination with circulating gold. If BAL is present in sufficient amounts before gold becomes combined with or deposited in tissues extensive cellular damage is prevented and life is sustained. The time element appears to be the most important factor in this competition for gold. Injections of BAL made soon after poisoning are effective; the same amount of BAL given later in the course of gold administration does not protect against lethal toxicity.

It appears clear therefore that to be most beneficial in human beings in combating toxicity resulting from therapeutic injections of gold salts BAL should be administered promptly when signs of toxicity are first observed; the longer the delay in use of BAL the less beneficial it likely will be. This is borne out in the clinical reports concerning BAL^{5,7} and in unpublished clinical observations of the authors. Ragan and Boots reported BAL to be effective in protecting rats against toxicity of gold. It is impossible to compare our results with theirs for no details of dosage or time relations were published in their report.

These animal studies suggest that the manner in which BAL acts to prevent toxicity due to gold is in all respects similar to its action against arsenic and mercury intoxication.⁸

SUMMARY

The toxicity from gold salts injected into albino rats is described. BAL had no protective effect when injected several days after toxic doses of gold were administered. When injected simultaneously with the administration of toxic doses of gold sufficient to be lethal to rats BAL prevented important toxicity; the animals lived in apparently good health. These observations indicate that BAL is an effective antidote for gold if it is given in adequate amounts sufficiently early after the administration of gold salts. These results

further suggest that to have maximal effect in human beings who have toxicity from gold salts, BAL should be given as soon as signs of toxicity are observed

THE EFFECT OF FEEDING PROPYLTHIOURACIL AND CHOLESTEROL ON THE BLOOD CHOLESTEROL AND ARTERIAL INTIMA IN THE RAT

L. HORICK* AND L. HAVEL†
CHICAGO, ILL.

ATTEMPTS to produce arteriosclerosis in the rat have uniformly met with failure. Cholesterol feeding per se has been attempted by many without appreciably affecting either the blood cholesterol levels or the arterial intima.¹

The nature of this resistance to the development of experimental atherosclerosis is unknown, and its elucidation is vital to the solution of the pathogenesis of the disease. That one of the factors involved in the process of resistance may be hormonal is suggested by the recent work of Steiner and Kendall who found that thiouracil and cholesterol fed to dogs will produce atherosclerosis, while either agent when fed alone will fail to do so. This work is highly significant because the dog does not normally develop atherosclerosis and the experimental variety of the disease has never previously been induced in this animal. Previous work has shown that the thyroid gland is involved in the entire process of experimental atherosclerosis. In rabbits thyroidectomy renders the animals far more susceptible to the cholesterolemia and atherosclerosis which follow the feeding of cholesterol.⁴ On the other hand feeding desiccated thyroid or potassium iodide seems to protect the animals against the development of cholesterol induced lesions and lowers the blood cholesterol levels.⁵ We have been able to confirm the protective action of desiccated thyroid in another species, the chicken.⁶ We also have observed the synergistic effect of cholesterol and thiouracil on raising the blood cholesterol levels of the chicken.⁶ With these considerations in mind we decided to use the antithyroid drug thiouracil in the rat in an attempt to break down the resistance of this species to the induction of atherosclerosis by cholesterol feeding.

PROCEDURE

White rats of the Harlan strain (originally Wistar) were used. They weighed approximately 100 to 150 grams at the start of the experiment. The rats were divided into six separate groups. Group 1 was maintained on a diet of dog biscuits† and water ad libitum. Group 2 received 5 per cent cholesterol suspended in cottonseed oil mixed with ground meal‡ and tap water. Group 3 received 10 per cent cholesterol mixed with the basal diet. Groups 4, 5, and 6 received propylthiouracil§ either alone or mixed with cholesterol in

*Five animals only

†Four animals only

mean weight of 139 grams. The normal control animals gained steadily in weight and had reached a peak weight of 328 grams at the conclusion of the experiment. The 5 per cent cholesterol animals gained steadily in weight and were somewhat heavier than the normal controls, weighing 404 grams. The groups which received propylthiouracil either alone or in combination with cholesterol were far lighter than any of the control groups. Thus the propylthiouracil group weighed 257 grams at the conclusion of the experiment and the 5 per cent and 10 per cent cholesterol-propylthiouracil groups 160 and 163 grams respectively. This correlates well with the figures obtained for food intake.

Blood Cholesterol Levels—The cholesterol values for the normal controls showed no significant changes throughout the course of the experiment. The highest and lowest average values recorded were 53.5 and 95 mg per cent respectively with a mean of 74.1 mg per cent. There was no trend toward an increase of the blood cholesterol levels with increasing age. The 5 per cent cholesterol fed group showed a slight rise in the blood cholesterol level by the fourth week of feeding. By the eighth week of feeding the blood cholesterol level had risen to an average value of 136 mg per cent and this was the highest average value attained by this group. Thereafter, it fell off gradually and fluctuated, but remained consistently higher than that of the controls. The blood cholesterol levels for the 10 per cent cholesterol fed group showed a rise parallel to and slightly greater than those in the 5 per cent cholesterol fed group. The highest average value for this group was 142 mg per cent and was achieved by the eighth week of feeding.

In the propylthiouracil control group the blood cholesterol levels rose to 82.4 mg per cent after four weeks of feeding, and subsequently rose to 167 mg per cent by the eighth week. Thereafter there was a fluctuating decline with the values in this group somewhat higher than those for the 10 per cent cholesterol fed group.

The 5 per cent cholesterol-propylthiouracil group showed an early rise of blood cholesterol levels to 97.2 mg per cent after four weeks of feeding, and then a progressive rise to a high average value of 373 mg per cent after sixteen to twenty weeks of feeding. Thereafter there was a gradual decline in the blood cholesterol levels. The highest blood cholesterol level in any individual in this group was 616 mg per cent and was achieved after twenty weeks.

TABLE III AVERAGE BLOOD CHOLESTEROL LEVELS OF DIFFERENT GROUPS IN MILLIGRAMS PER CENT

GROUP	NUMBER OF WEEKS ON DIET							
	0	4	8	12	17	22	27	31
Normal	54*	54	81	66	95	80	88	65
5 per cent cholesterol		77	136	102	107	113	95	81
10 per cent cholesterol		86	142	95	130	129	113	118

5 per cent cholesterol propylthiouracil		97	200	250	373	315	152	158
10 per cent cholesterol propylthiouracil		155	254	283	345	305	114	288

Average control value for all groups

weeks on the diet. The 10 per cent cholesterol propylthiouracil group showed the greatest early rise in the blood cholesterol of any of the groups with a level of 155 mg per cent after four weeks of feeding. This was almost three times the average control level. The blood cholesterol level rose steadily thereafter to 345 mg per cent after sixteen to twenty weeks of feeding and then declined gradually.

In summary then the feeding of either cholesterol or propylthiouracil alone in the dosage employed resulted in each case in a slight rise of the blood cholesterol levels above the normal. Five and ten per cent cholesterol in the diet produced rises in the blood cholesterol levels which were similar when the entire time course of the experiment is surveyed. When the cholesterol and propylthiouracil were combined in the diet the rise in blood cholesterol was significantly greater than in the preceding groups. The combination of 10 per cent cholesterol with propylthiouracil gave somewhat higher levels during the first twelve weeks of the experiment than the 5 per cent cholesterol combined with propylthiouracil. The high average values on all diets were achieved before the twenty second week of feeding and tended to decline thereafter. This correlates with a tendency on the part of the animals to refuse of further weight gain, decreased food intake, and generally poor health which became apparent at this time.* Toward the end of the experiment it was necessary to substitute ordinary Friskies for the prepared feed for a few days at a time because of the sickly appearance of the rats. Propylthiouracil alone produced a cholesterol emia equal to that produced by cholesterol alone. When cholesterol and propylthiouracil were combined in the diet the rise in the blood cholesterol was significantly greater than in the preceding groups. There was a moderate hypercholesterolemia which was approximately six times the average normal values or even ten times the control value in single animals. Increasing the cholesterol content of the propylthiouracil cholesterol mixture does not appreciably increase the cholesterolemia obtained.

Pathologic Findings—None of the animals showed any gross atherosclerotic lesions of the intima of the aorta or of the valves of the heart or of the major

It would appear then that the feeding of cholesterol alone in excess of 5 per cent of the diet does not produce any appreciably greater cholesterolemia than that produced by 5 per cent cholesterol or perhaps even lesser amounts of cholesterol in the diet.

the basal diet. The dose of propylthiouracil employed was 0.2 per cent at the start, it was increased to 0.3 per cent after fifteen weeks, and to 0.4 per cent after an additional five weeks. Propylthiouracil was dissolved and suspended in the drinking water in a concentration of 0.1 per cent. Group 4, consisting of eight rats, received the basal diet plus propylthiouracil in the dosage outlined. Group 5, consisting of twelve rats, received the basal diet plus propylthiouracil and 5 per cent cholesterol in oil. Group 6, consisting of eight rats, received the basal diet plus propylthiouracil and 10 per cent cholesterol in oil. In order to increase the food intake and to prevent scattering, milk powder and water were used as a binder and the feed was prepared in cake form. The amount of milk powder utilized amounted to approximately 20 per cent by weight of the total feed and added substantially to the protein and caloric value of the feed. The animals were weighed at intervals of three weeks and the blood cholesterol levels determined at that time. Two animals were chosen at random from Group 1 for cholesterol determinations and four animals from each of the other groups with the exception of Group 5, from which six animals were chosen at random for the cholesterol determinations. Blood was obtained from the tail vein, and the Schoenheimer-Sperry technique⁷ was used for total cholesterol determination. Food and water consumption data were collected in each group at intervals of three weeks throughout the experiment. All animals were autopsied and all organs examined. Special attention was paid to the heart and aorta which were removed en bloc, slit open with fine scissors and carefully examined for evidence of atheroma. Hematoxylin and eosin stained sections were made only of those aortas which appeared to show gross evidence of atheroma.

RESULTS

Food Intake—Data in Table I indicate that the normal rat consumed 41 to 42 Gm of food in twenty-four hours. The water consumption during the same period was 27 to 42 cc per rat. The food consumption of the 5 and 10 per cent cholesterol fed rats approximately equalled that of the controls, with intakes of 20 to 39 and 20 to 47 Gm per rat per day respectively. The food intake for these rats was somewhat lower than for the control group, with a more marked discrepancy in the 10 per cent cholesterol fed group. The animals receiving propylthiouracil, either alone or in combination with cholesterol, had a lower food intake than either the normal controls or the cholesterol controls. The intake for the propylthiouracil group ranged from 20 to 28 Gm per rat per day of food and 11 to 30 cc of water. The intake of the 5 per cent cholesterol-propylthiouracil group was 14 to 21 Gm per rat per day and 14 to 30 cc per rat per day, and of the 10 per cent cholesterol-propylthiouracil group 16 to 19 Gm per rat per day and 13 to 20 cc per rat per day. It is apparent that the intake of food and water in the two latter groups was approximately half that of the control groups.

Body Weight—The data are shown in Table II. At the commencement of the experiment, the animals weighed between 111 and 153 grams with a

arterial trunks Fatty liver was a common finding in most of the animals which received either cholesterol or thioracil alone, or the combination None of the control rats showed evidence of fatty liver

DISCUSSION

The feeding of diets containing cholesterol in high concentration, alone or combined with propylthiouracil, failed to produce atherosclerosis in the rat The diets employed resulted in rises in the blood cholesterol levels,* but the levels found did not approach those obtained by Steiner and Kendall in the dog or by ourselves in the chicken⁸ We have been able to demonstrate in the chicken that the development of atherosclerosis is in fairly close relationship to the degree of hypercholesterolemia and its duration⁸ We may assume that the inability to produce a hypercholesterolemia comparable to that seen in Steiner and Kendall's dogs and in our chickens is responsible *in part* for the failure of the rats to develop evidence of atheromatosis However, it must be noted that cholesterol levels similar to those obtained in the rats in this experiment and maintained for similar periods of time would produce atheromatous changes in both the rabbit and in the chicken^{8, 12} The failure of the rats to develop atheromatosis must be attributed in part to a cholesterol metabolic mechanism different from that which prevails in rabbits and chickens

Feeding cholesterol in excess of 5 per cent of the total diet did not produce any further rises in the blood cholesterol and this may indicate that there is a threshold for the absorption of cholesterol from the gastrointestinal tract Cholesterol fed in excess of this threshold concentration is probably excreted unchanged in the feces Equally tenable hypotheses are (1) Storage of the additional cholesterol outside the blood stream, (2) endogenous destruction of the additional cholesterol, (3) diminished endogenous synthesis of cholesterol to balance the additional amount ingested, (4) excretion of the additional amount ingested via the bile and the gastrointestinal tract Only complete cholesterol balance studies can clear up this important question

Cook and McCulloch⁹ fed rats diets containing 2 per cent cholesterol and observed a threefold elevation in the blood cholesterol levels This is comparable to the elevation we obtained by adding 5 and even 10 per cent of cholesterol to the diet Cook's balance studies on cholesterol fed rats receiving 2 per cent cholesterol indicated that 30 per cent of the ingested cholesterol could not be accounted for and that the remainder was in the carcass, liver, and feces He also calculated that the rats absorbed 0.3 to 0.4 Gm per kilogram per day of cholesterol If we consider the average daily food intake of our rats receiving 10 per cent cholesterol as 30 Gm, then they ingested 3 Gm of cholesterol per day It is probable that nine tenths of this cholesterol passed through the gastrointestinal tract without being absorbed, although proof of this awaits cholesterol balance

*Since no pair fed controls were used in this experiment we cannot unequivocally rule out the possibility that the relative undernutrition of the thioracil fed rats may have resulted in cholesterolemia Other investigators however have found that in the rat¹³ and dog¹⁴ does not cause any change in the blood cholesterol levels Likewise chronic undernutrition in the dog¹⁴ does not cause any significant change in blood cholesterol levels

studies. It is of interest that the same threshold phenomenon has been observed in the chicken, where cholesterol fed in excess of 1 per cent of the diet does not cause any further rise in the blood cholesterol level.⁸

The combination of cholesterol with propylthiouracil produced a synergistic rise in the blood cholesterol levels. The mechanism for this synergism is not well understood. Fleischmann and Shumacker¹¹ believe that thyroid hormone causes a shift of cholesterol from the blood into the tissues without influencing the total amount of cholesterol in the body. Conversely then thiouracil by inhibiting the thyroid hormone should arrest this procedure or perhaps reverse its direction thereby resulting in an increase of cholesterol in the blood.

It has been reported by several observers^{9, 10} that cholesterol feeding in the rat results primarily in an increase of the combined cholesterol in the liver with only slight increases in the cholesterol content of other organs. Sperry and Stoyanoff¹⁰ found that in their rats which received a 1 per cent cholesterol diet as much as 50 per cent of the total body cholesterol was concentrated in the liver. They concluded that omnivores such as the rat did not differ appreciably from the herbivores in their ability to absorb cholesterol and deposit it in the tissues, but that they differed markedly with respect to cholesterol deposition in the arteries.

Thus, while thiouracil fed to the dog diminished the resistance of that animal to cholesterol induced atherosclerosis it failed to do so in the rat. Two possible reasons for this may be considered: (1) We did not use sufficient amounts of propylthiouracil to really disturb the thyroid mechanism (however in the rat it is difficult to give much greater doses of propylthiouracil than those employed here without causing toxic symptoms to appear), and (2) in the rat other as yet unknown factors may be involved in this resistance phenomenon which were not affected by the conditions of this experiment.

It would appear then that new avenues of approach must be opened. A combination of endocrine inhibition involving more than one of the endocrine organs concerned with lipid metabolism may shed further light on this problem.

SUMMARY

The feeding of diets containing either cholesterol alone in concentrations of 5 to 10 per cent or propylthiouracil alone in concentrations of 0.5 to 0.6 per cent, or both combined, for periods up to thirty eight weeks failed to produce vascular lesions of the arteriosclerotic variety in rats.

The feeding of cholesterol or propylthiouracil alone produced a cholesterol emia of two to three times the normal values. Combining both gave average values approximately six times normal average values and as much as ten times normal for individual rats.

Cholesterol in excess of 5 per cent did not produce any further rise in the blood cholesterol levels. Results of feeding 5 and 10 per cent cholesterol combined with propylthiouracil compared closely with one another.

Propylthiouracil did not succeed in breaking down the rat's resistance to cholesterol-induced atherosclerosis. The resistance to atherosclerosis in this animal is probably dependent on other factors in addition to the thyroid gland and its secretions.

We are indebted to Dr L N Katz for his suggestions in pursuing this study and to the other members of the department for their invaluable help in executing the studies.

LABORATORY METHODS

USE OF SPLENIC INFUSION AS A BASE FOR GROWING CERTAIN PATHOGENIC MICROORGANISMS

RALPH MCBURNEY, BS MS MD MPH AND LOUISE R CLAYSON
AB MA MT, (ASCP)
BIRMINGHAM ALA

NUMEROUS methods for isolating and/or preserving certain microorganisms in their original state for long periods of time have been the object of many investigations

Lloyd¹ showed that certain accessory growth factors were essential to primary isolation of *Neisseria intracellularis* and that subsequent to isolation, provided an abundant supply of free amino acid was present the organisms gradually developed a change in metabolism becoming increasingly independent of the so called vitamin content in the medium. The results of Cole and Lloyd² showed that the growth of *Neisseria gonorrhoea* was considerably dependent upon hydrogen ion concentration (the mean optimum being pH 7.6) concentration of amino acids, and the presence of certain accessory growth factors or vitamins

Numerous investigators have reported various media supplying accessory growth factors. Worth,³ in an effort to provide a universal medium for promoting growth and keeping fastidious microorganisms viable used a nutrient gelatin containing peptone and sodium chloride. Spray⁴ found that certain fastidious organisms grew well upon a hormone gelatin agar to which sodium caseinate and soluble starch were added. James found that a 20 per cent infusion of the quahaug, a species of hard shelled clam was an excellent source of growth promoting factor for many of the more fastidious microorganisms

The lyophile and cryochem methods of Flosdorf and Mudd⁵ employing the principle of freezing and rapid dehydration in vacuo are recognized as superior for the preservation of cultures but the costs of elaborate equipment and the time and effort expended in maintaining large collections of microorganisms may be prohibitive. The maintenance of bacteria by overlaying the culture with sterile paraffin oil as recommended by Morton and Pulaski⁶ has advantages but necessitates the use of special selective media for primary growth

For general and ready use any culture medium that is simple to prepare that can be sterilized in the autoclave without subsequent addition of body fluids and in which the most fastidious microorganisms will grow luxuriantly and remain viable would be ideal. The employment of beef spleen as a growth promoting factor has fulfilled this need in our own investigations

From the Department of Bacteriology and Clinical Pathology Medical College of Alabama.

Received for publication April 1 1948

Spleen as a source of growth-promoting factor was suggested by the work of Cole and Lloyd² who used a tryptic digest of casein with extract of pig pancreas, which they named tryptamine, and an infusion of beef spleen for growing *N gonorrhoeae*. It was further suggested by Zinsser and Bayne Jones³ who state that Neufeld found that pneumococci remained viable in the desiccated spleens of infected mice for periods far exceeding those on selected media.

To further determine the value of spleen as a factor in growth and viability, the following experiments were conducted.

PROCEDURE

Cultures of eleven of the more fastidious organisms for viability studies were made on various media consisting of splenic infusion agar, splenic infusion gelatin, beef infusion agar, and beef infusion gelatin in varying amounts, with and without the addition of vitamin B₁. Splenic infusion base was prepared in a manner similar to the preparation of beef infusion base, the usual amount of peptone and sodium chloride being added to filtered minced beef spleen infused overnight. The pH was adjusted to 7.6 before autoclaving. Ten per cent gelatin was added to the splenic infusion medium and both 10 and 15 per cent gelatin to the beef infusion medium. When vitamin B₁ was employed in the medium it was sterilized by Seitz filtration and subsequently added aseptically in a 10 per cent concentration.

The organisms used were three strains of streptococci (*Streptococcus pyogenes*, *Streptococcus viridans*, *Streptococcus anhemolyticus*), three of pneumococci (*Diplococcus pneumoniae* Types 1, 2, and 3), and one each of *Neisseria intracellularis*, *Neisseria gonorrhoeae*, *Hemophilus pertussis*, *Corynebacterium diphtheriae*, and *Hemophilus influenzae*.

All media were tubed in plastic screw-top vials, 120 by 20 mm, to insure the preservation of moisture during incubation and storage. Prior to inoculation of experimental media, three successive transfers of each organism were made twenty-four hours apart upon selective media for each species.

Inoculations were done with a standard 3 mm loop from an emulsion of the test organism in mammalian Ringer's solution made to a density corresponding to McFarland nephelometer tube No. 8. This was to insure uniformity of the inoculum of each organism and to prevent a carry-over of nutrient material from the selective medium on which the organisms were growing.

Five tubes of each type of medium were inoculated with the various organisms. After forty-eight hours of incubation at 37° C, growth of each was recorded, the tubes were sealed and placed in the refrigerator at 10° C, with the exception of *N intracellularis*, *N gonorrhoeae*, and *H influenzae*. The first two were kept in the incubator at 37° C, the tubes of the latter were immersed in cold water and placed in a dark cupboard at 20° C. Growth in each instance was indicated as negative (-), good (+), and heavy (++) Table I shows the record of growth on various media with appropriate symbols.

With the exceptions of *H. influenzae* and *H. pertussis* splenic infusion media in every instance, both with and without vitamin B₁, gave rise to excellent initial growth, which was superior to that on beef infusion media.

TABLE I PROFUSION OF GROWTH OF ORGANISMS AFTER 100% FROM HOURS OF INCUBATION

ORGANISM	SPLenic INFUSION BASE				BEEF INFUSION BASE			
	SLA	SLAV	SLG	SLGV	BLAV	BL10V	BL15	BL15V

<i>H. pertussis</i>	-	-	-	-	-	-	-	-
<i>C. diphtheriae</i>	++	++	++	++	++	+	++	++

SLA Splenic infusion agar, SLAV splenic infusion agar with vitamin B₁, SLG splenic infusion gelatin 10 per cent, SLGV splenic infusion gelatin 15 per cent plus vitamin B₁. BLAV beef infusion agar, BL10V beef infusion gelatin 10 per cent plus vitamin B₁, BL15 beef infusion gelatin 15 per cent plus vitamin B₁.

Transfers from each type of medium were made at intervals of one and one half, three, six, nine and twelve months to determine viability. They were made from suspension in Ringer's solution from the growth in the sealed stored tubes and also by direct transfer to selective media.

Additional studies on splenic medium were made to determine its value as a base for blood agar, its ability to support growth of the pathogenic clostridia and its use in primary isolation of organisms. For this purpose Petri dish streak cultures of *Str. viridans*, *D. Pneumoniae*, *Str. pyogenes*, *C. diphtheriae* and *N. intracellularis* were made on plain splenic agar, splenic blood agar and plain blood agar in order to compare growth and colonial characteristics. Pathogenic clostridia, *Ct. botulinum*, *Ct. tetani* and *Ct. novyi* were grown in deep slabs of splenic infusion agar and broth to determine whether these media would warrant their use for growing anaerobes. Studies on splenic infusion agar were made to evaluate its use in primary isolation of organisms from sputa, nasal washings, and throat cultures. Microorganisms so isolated were grown on splenic infusion agar and vaccines were prepared from these.

RESULTS

Str. pyogenes was found viable on all media except beef infusion gelatin 10 per cent plus vitamin B₁. *Str. viridans* was living only on beef infusion gelatin 15 per cent and beef infusion gelatin 15 per cent plus vitamin B₁, and *Str. anhemolyticus* was living on all the cultural media at the end of one and one half months. *Str. anhemolyticus* was living on all media and *Str. pyogenes* only on the splenic infusion agar both with and without vitamin B₁ at the end of twelve months, whereas *Str. viridans* failed to remain alive longer than three months at which time it was living only on beef infusion gelatin 15 per cent. See Table II.

It will be noted from these results that the strain of *Sti anhemolyticus* employed survived on all types of media for the entire period of the experiment (twelve months) and that *Sti pyogenes* was maintained on splenic infusion agar for a period of one year, but that *Sti viridans* did not survive on any form of splenic media

TABLE II SURVIVAL TIME OF ALL ORGANISMS TESTED ON SPLENIC AND ON BEEF INFUSION MEDIA AT VARIOUS INTERVALS

	D pneumoniae 1	-	-	+	+	-	-	+	+
	D pneumoniae 2	-	-	+	+	-	-	+	+
	D pneumoniae 3	-	-	+	+	-	+	+	+
	C diphtheriae	+	+	-	+	-	-	+	+
6	Str pyogenes	+	+	-	-	-	-	+	+
	Str anhemolyticus	+	+	+	+	+	+	+	+
	D pneumoniae 1	-	-	+	+	-	-	+	+
	D pneumoniae 2	-	-	+	+	-	-	+	+
	D pneumoniae 3	-	-	+	+	-	+	+	+
	C diphtheriae	+	+	-	-	-	-	+	+
9	Str pyogenes	+	+	-	-	-	-	+	+
	Str anhemolyticus	+	+	+	+	+	+	+	+
	D pneumoniae 3	-	-	-	+	-	-	-	-
	C diphtheriae	+	+	-	-	-	-	-	-
12	Str pyogenes	+	+	-	-	-	-	-	-
	Str anhemolyticus	+	+	+	+	+	+	+	+

The three strains of *D pneumoniae* survived as follow At the end of one and one half months, all strains, with the exception of *D pneumoniae* 1 on beef infusion gelatin 10 per cent plus vitamin B₁, were alive on all media At the end of six months, survival was recorded on the splenic infusion gelatin, but not on the splenic agar By the end of nine months all cultures had died

C diphtheriae was viable following storage on splenic infusion agar for nine months On the other hand, similar cultures on any of the beef infusion media failed to survive *N intracellularis* and *N gonorrhoeae* were alive at one and one half months on splenic agar Both of these organisms usually require transfers every forty-eight to seventy-two hours on chocolate agar, the medium of choice for their growth Splenic medium was not conducive to the growth of *H pertussis* or *H influenzae*

Alpha hemolysis of *Str. viridans* and *D. pneumoniae* and beta hemolysis of *Str. pyogenes* were readily distinguishable on splenic blood agar. Colonies of these organisms on splenic blood agar were larger than the usual pinpoint ones on plain blood agar, and the zone of hemolysis was more readily discernible

Fig. 1

Growth and hemolysis were both marked in less than twenty four hours. Fig. 1 illustrates the excellent growth of these organisms upon plain splenic and splenic blood agar, and the exceptional colony growth and hemolytic action of *Str. pyogenes* on splenic blood agar compared with that upon plain blood agar. The addition of blood to the splenic medium except for detecting hemolysis, offers no particular enhancement to the growth.

The clostridia were grown in deep stabs of splenic infusion agar and in splenic infusion broth. Growth was excellent and compared favorably with that in ground beef medium or broth to which sterile tissue had been added. Blackening of the agar and broth occurred in deep strata of the medium in a manner similar to the blackening action in brain medium and gelatin as ordinarily observed in certain of the anaerobes.

The protuse growth on splenic infusion media of the organisms studied except *H. pertussis* and *H. influenzae*, has proved excellent for primary isolation and for the preparation of certain bacterial vaccines. Plain splenic infusion agar furnishes suitable growth for laboratory teaching.

SUMMARY AND CONCLUSIONS

Spleen infusion as a base for agar has been used satisfactorily for maintaining cultures of certain strains of streptococci, *C. diphtheriae*, *N. intracellularis*, and *N. gonorrhoeae* over periods of time in excess of the usual limits for carrying stock cultures of these organisms.

Transfers for carrying stock cultures of most of the fastidious organisms may be made at intervals of one to two months or longer, instead of at weekly or shorter intervals.

A universal medium such as splenic agar is easily prepared, requires no subsequent addition of body fluids, and eliminates the preparation of selective media for growth of each type of the more fastidious organisms to be cultivated.

Luxuriant growth of most of the blood-loving organisms on this medium exceeds that on a selective medium in each instance. Splenic medium has proved excellent for primary isolation and the preparation of bacterial vaccines. Splenic infusion as a base for broth, agar, or gelatin has been used successfully in classroom work. Pathogenic clostridia grow well in these media.

No studies have been made to determine what growth factor or factors may be present in spleen. Apparently the amino acids in the commercial peptone present, released during bacterial development, plus growth factors from the splenic infusion provide excellent nutrient material. No observable advantage is gained through the addition of vitamin B₁ to splenic media. The preservation of moisture by the use of tightly sealing plastic caps makes possible storage of this medium for several months.

AN IMPROVED MOUNTING FOR THERMOCOUPLES FOR THE MEASUREMENT OF THE SURFACE TEMPERATURE OF THE BODY

EDWARD D. PALMIS, PH.D., and CHARLES R. PARK, M.D.
FORT KNOX, KY

INTRODUCTION

THE intensity of radiation, measured by a radiometer, provides the best index of the temperature of the outermost surface of the skin. The radiometer is an accurate instrument but is technically difficult to employ; it requires daily calibration, the conversion of electric potentials to temperature is laborious, and an observer or trained subject must hold the instrument in position for each reading. Thermocouples, on the other hand, are technically easy to use, but give inaccurate measurements of surface temperature. This is the result of the type of mounting employed. When a naked thermal junction is used, readings are affected by the temperature of the ambient air, and firm contact between the junction and the skin is difficult to maintain. When the thermocouple is protected from the air by a covering, heat loss from the skin is impeded and the readings are too high. The difference between surface temperature measurements by thermocouple and radiometer is generally 1° to 3° C.¹

APPLIANCE

A thermocouple mounting was developed which allowed the skin surface temperature to be determined with much greater accuracy than previously. This mounting (Fig. 1) was made on a 1 by 3 inch rectangle of copper window screen (16 mesh, wire diameter 0.01 inch). Copper-constantan thermocouple wire* was used, and kinking was prevented by plastic spaghetti. Insulation was retained to just beyond the point where the wires passed under the screen, and the insulated portion was lashed to the screen with thread. The naked leads were twisted together and the junction, about one-half inch in length, was soldered to the under side of the screen as indicated. The screen remained quite flexible except for the ends, which were dipped in soft solder to provide firm connections for metal snap buttons. Adjustable bands of elastic cloth were attached to these buttons and held the mounting firmly against the skin.

RESULTS

Surface temperature measurements using these assemblies were compared with readings obtained by radiometer in four different environments. Thermocouples were fastened to the belly, chest, and thighs of nude subjects and temperatures on adjacent skin areas were determined simultaneously by both

From Medical Department Field Research Laboratory

Received for publication April 21 1948

*The most satisfactory wire was nylon-insulated 7 strand 36 gauge obtained from Revere Corporation of America, Wallingford, Conn.

Fig 1—The thermocouple assembly

Fig 2—Comparison of simultaneous thermocouple and radiometer measurements of surface temperatures.

methods. The results are shown in Fig 2. The broken lines on each side of the central diagonal show the limits of variations of plus minus 1°C between the readings by each method and enclose 95 per cent of all measurements. It was not possible to measure temperature by both methods simultaneously on

exactly the same skin area, and, since the skin temperature may be appreciably different in immediately adjacent areas, a better comparison between the methods is made by comparing the average of a series of readings. Such averages are shown in Table I.

TABLE I COMPARISON OF THERMOCOUPLE AND RADIOMETER READINGS

ROOM TEMPERATURE (° C)	NUMBER OF VALUES	AVERAGE SURFACE TEMPERATURE (° C)		DIFFERENCE (° C)
		THERMOCOUPLE	RADIOMETER	
29	16	34.9	35.0	-0.1
32	23	34.2	34.2	0.0
38	24	35.4	35.0	+0.4
43	28	37.1	36.5	+0.6

The room temperature still affected the thermocouple readings slightly in the hot environments. The subjects were sweating profusely at these temperatures, and the difference in readings presumably resulted from impaired evaporation. The agreement between radiometer and thermocouple, however, was markedly superior under these circumstances to the agreement when either naked, covered, or partially covered thermocouples with conventional mountings were used. The screen mounting always remained firmly in place despite muscular movement or heavy sweating.

SUMMARY

Thermocouples mounted on copper window screen were designed for the measurement of the skin surface temperatures of human subjects. In environments ranging from 29° to 43° C the average deviation of a series of thermocouple readings from a simultaneous series of radiometer readings was -0.1° C in the coolest environment and only +0.6° C in the hottest. The assemblies were easily constructed, they always remained firmly in place and were quite sturdy.

STUDIES OF PANCREATIC FUNCTION

IV A SIMPLIFIED METHOD FOR THE DETERMINATION OF SERUM LIPASE USING AQUEOUS TRIBUTYRIN AS SUBSTRATE WITH ONE HUNDRED NORMAL VALLES BY THIS METHOD

NORMAN P. GOLDSTEIN M.D., JEROME H. EPSTEIN B.A. AND
JOSEPH H. ROE PH.D.
WASHINGTON D.C.

IN 1943 Goldstein and Roe¹ published a procedure for estimating serum lipase in which the conditions for the enzymic action were so improved that only one hour's incubation at 37° C. was necessary. In this procedure the substrate was dispersed with bile in the digestion mixture. At that time it was observed that the substrate, tributyrin, could be satisfactorily dispersed in an aqueous medium since tributyrin is slightly soluble in water. Preliminary experiments revealed that if tributyrin is properly homogenized in an aqueous buffered digestion mixture, it is split more rapidly by blood serum than when it is emulsified with bile or bile salts. It seemed desirable to take advantage of this observation since the end point of the titration with the aqueous suspension is more easily discerned and the difficulty of preparing and titrating a bile emulsion is eliminated.

Since previous observations were made with cat serum as the source of the enzyme it was felt that the experiment should be repeated using the sera of human subjects. We repeated this work using the sera of four students all apparently in good health. The tributyrinase concentration of each sample of serum was determined in three ways: (1) using the glycerol bile emulsifying agent as reported in our previous paper; (2) substituting 5 c.c. of distilled water for the glycerol bile mixture; (3) omitting the glycerol bile and thus reducing the volume of the digestion mixture by 5 cubic centimeters. The results of this study are recorded in Table I. Our data show that human sera respond in the same way as cat sera to the omission of the glycerol bile emulsifying reagent. This study also demonstrates that it is not necessary to substitute the distilled water for the glycerol bile. The determinations were carried out under the conditions outlined in our previous paper.¹

In order to be sure that this difference in the measurement of tributyrinase activity of human sera represented the limitations of bile and not a difference in the hydrogen ion concentration of the digestion mixtures caused by the presence or absence of bile, it was necessary to determine the pH of the digestion mixtures before and after hydrolysis. We carried out this experiment using a pH paper method.* The data presented in Table II demonstrate that the differences in hydrolysis are not caused by significant differences in the pH of the digestion mixtures.

Omission of glycerol bile	8.4	8.2

The new method developed with the use of an aqueous tributyrin emulsion is described below

MODIFIED METHOD FOR SERUM TRIBUTYRINASE DETERMINATION

Reagents—

Substrate Tributyrin *

Buffer Dissolve 5 Gm of sodium diethylbarbiturate in distilled water and make up to 1 liter

Calcium Acetate Solution 20 Gm of calcium acetate, chemically pure $\text{Ca}(\text{CH}_3\text{COO})_2 \cdot \text{H}_2\text{O}$, are dissolved in distilled water and the solution is made up to 1 liter

Alcohol-Ether Inactivating Mixture To 900 cc of 95 per cent ethyl alcohol add 100 cc of ether

Indicator Dissolve 1 Gm of phenolphthalein in 100 cc of 95 per cent alcohol

Standard Alkali A 0.05N solution of potassium hydroxide is prepared

Procedure—Pipette 0.75 cc of tributyrin, 30 cc of the sodium diethylbarbiturate solution, and 30 cc of the calcium acetate solution into the receptacle of a hand homogenizer† and pass this mixture through the hand homogenizer three times. Then pipette 20 cc portions of the emulsion into two large test tubes, one the control and the other the experimental. Both the control and experimental tubes are placed in a constant temperature water bath at 37° C, and when the emulsions have reached this temperature 1 cc of the serum is pipetted into the experimental tube and mixed thoroughly with the emulsion by means of a stirring rod. After one hour of hydrolysis, 1 cc of serum is pipetted into the control tube and the enzyme in both tubes is inactivated by pouring each mixture into a 250 cc Erlenmeyer flask containing 100 cc of the alcohol-ether mixture. The contents of each flask are then titrated with the standard potassium hydroxide solution, using phenolphthalein as the

*Eastman Kodak Company Rochester N. Y.

†Schaar and Company Chicago Ill.

indicator, to the same shade of light, but definite pink color. The difference between the two titration values is a measure of the concentration of lipase in the serum. In agreement with conventional methods of designating blood values, we have expressed our results in terms of concentration of enzyme per 100 cc of serum. One tributyrinase unit is the amount of enzyme that will catalyze the hydrolysis of tributyrin with the release of 1 cc of 0.1N fatty acid in one hour at 37° C with the reagents and conditions as described.

TABLE III ELECTROMETRIC TITRATION OF SERUM TRIBUTYRINASE CONCENTRATION (RABBIT SERUM)

SERUM	pH AT POINT OF INACTIVATION	pH AT END POINT OF TITRATION	0.05 KOH (cc)	TRIBUTYRINASE UNITS
Control	9.60	10.65	1	—
Experimental	9.35	10.65	3.01	55

The final step in this procedure the titration can be carried out more accurately as an electrometric titration. We have found the use of a Peelman calomel glass electrode pH meter (model H 2) in conjunction with an electric stirrer very satisfactory for this titration. In the electrometric titration the end point is at pH 10.65, this corresponds to the end point of the phenolphthalein titration. The difference in the hydrogen ion concentrations at which phenolphthalein turns pink in an aqueous solution (pH 8.3) as compared with an alcohol ether medium is due to the suppression of ionization in the alcohol ether mixture. An example of the electrometric titration for determining serum tributyrinase concentration is presented in Table III.

SERUM TRIBUTYRINASE CONCENTRATION IN ONE HUNDRED NORMAL HUMAN SUBJECTS

Using the technique as outlined we have determined the tributyrinase concentration of the serum of one hundred persons including medical students, graduate students, and faculty members. The group consisted of eighty six men and fourteen women, all apparently in good health. The ages of the group varied roughly from 20 to 50 years, with the majority of the group being in the 20 to 30 year range. All of the samples of blood except seven were drawn in the postabsorptive state, evidence at this time indicates no significant difference in the level of serum tributyrinase before and after meals.

The results of this study of serum tributyrinase levels in one hundred healthy subjects are graphically shown in Fig. 1. The lowest value of this group was 81 tributyrinase units, while the highest concentration was 246 tributyrinase units. There were only three samples of serum with values below 100 tributyrinase units, then there was a sharp rise in the number of samples of serum with values ranging from 100 to 180 tributyrinase units. This was followed by a sharp fall in the number of samples (nine) of serum with values over 180 units. Thus 88 per cent of the samples of serum showed a tributyrinase concentration ranging from 100 to 180 units. Further analysis of these values showed the mean normal to be 146.26 the standard deviation to be 0.05, and the standard error to be 3.01.

Analysis of the values of serum tributyrinase when the samples were divided as to the sex of the donor gives one the impression that the serum tributyrinase of women is decidedly lower than that of men. Fig. 1 portrays this graphically. It is readily observed that the majority of female values fall between 100 and 150 units, the mean normal for the female group was 121.14, the standard deviation 19.11, and the standard error 5.11. When the male group is analyzed it is seen that the majority of values fall between 100 and

FIG. 1.—Distribution of serum tributyrinase values of one hundred normal human subjects. The height of the column represents the total number of subjects; the area in black, the number of women; and the difference between the two, the number of men.

180 units, the mean normal for the male group was 150.42, the standard deviation 29.45, and the standard error 3.18. In spite of the great discrepancy between the number of samples of serum from men (eighty-six) and those from women (fourteen), the difference between the serum tributyrinase levels of the two sexes is found to be significant when subjected to statistical analysis using the method of the difference between two means ($t = 2.928$, therefore $P < 0.01$).

Utilizing the data further, it can be observed that the 5 per cent fiducial limits for the one hundred determinations of serum tributyrinase will be from 86.55 to 205.97 units. In general it may be inferred that our normal range more roughly will have 85 as the lower limit and 205 as the upper limit. With this range, 97 per cent of the samples of serum have a tributyrinase concentration that can be considered to be within normal limits, 1 per cent is below the lower limit, and 2 per cent are above the upper limit.

SUMMARY

A modification of the serum tributyrinase method eliminating the use of bile or bile salts, has been developed

The final step in the procedure the titration of the fatty acid may be carried out either with phenolphthalein as the indicator or electrometrically

The serum tributyrinase level of one hundred normal subjects has been determined

The range of tributyrinase values for the male subjects was higher than that of the female group

The normal range of serum tributyrinase levels was found to vary from 80 to 200 units

A CLINICAL METHOD FOR THE DETERMINATION OF HUMAN ALBUMIN BY MEANS OF A PRECIPITIN REACTION

BACON F. CHOW, PH.D., F. HOMBURGER, M.D., SHIRLEY DEBIASE, and
MARY L. PETLRMAN, PH.D.
NEW BRUNSWICK, N. J.

THE need for a rapid and accurate method for the estimation of human albumin in serum or other body fluids in the routine clinical laboratory has long been felt. Among those available methods* which might be adapted to such a purpose are the salt fractionation method of Howe,¹ the methanol precipitation method of Pillemer and Hutchinson,² the immunologic method,³ and electrophoretic analysis with the Tiselius apparatus.⁴ Although several modifications⁵⁻⁶ have been introduced into Howe's original technique, no procedure which permits a clear-cut separation of albumin and globulins has yet been devised. The chief purpose of our studies is to demonstrate that the precipitin method yields results which approach the accuracy of electrophoretic analysis, the generally accepted standard, and exceeds the other methods in speed, accuracy, and the saving of labor. Furthermore it permits an accurate determination of albumin present in body fluids in an amount too small to be determined by any other means. The results to be reported in this communication were collected for a period of more than a year from routine analyses in the laboratories of the Squibb Institute for Medical Research and the Sloan Kettering Institute for Cancer Research.

The principle of the immunologic method is based on the finding that the turbidity produced as a result of the reaction between human albumin and its homologous rabbit antiserum can be used as a measure of the precipitinogen present.

The method for the preparation of the human albumin antigen and the protocol for the immunization of rabbits have been given in a previous paper.³ A few modifications which have been introduced into the procedure for the albumin determination are described in detail here, and the results of a number of albumin determinations made by the most widely used chemical methods have been included for comparison.

METHODS

Standardization of Pooled Antihuman-Albumin Rabbit Sera—Each pool of antihuman-albumin rabbit sera was standardized by measuring the turbidity

From the Division of Protein Chemistry, The Squibb Institute for Medical Research, New Brunswick, N. J., and the Sloan-Kettering Institute for Cancer Research, New York, N. Y.
This study was aided in part by grants from the National Cancer Institute of the National Institute of Health, United States Public Health Service, by the Teagle Fellowship Fund, the Finney Howell Foundation, Baltimore, Md., and the James Foundation Incorporated, New York, N. Y.

The authors are indebted to Miss Lois Hall for technical assistance in the determination of albumin by the immunologic method and to Mrs. Barbara Gotthieb for making the electrophoretic analysis.

Received for publication May 17, 1948

*The method of Milne⁶ was published after the collection of our data was started and therefore was not included in this series.

of the immune precipitate produced by the addition of known amounts of human albumin (ranging from 5 to 50 μg of albumin nitrogen) to a sufficient amount of antiserum (2.0 ml) to insure an excess of antibody. Thus 1 per cent human albumin solution containing 1.474 mg. nitrogen per milliliter by Kjeldahl analysis was prepared by dissolving 1.0 Gm. of electrophoretically homogeneous human albumin in about 50 ml. of 0.85 per cent NaCl solution. This solution was neutralized with enough sodium bicarbonate (approximately 25 mg.) to bring the pH of the solution to 7.6 and then made up to a volume of 100 milliliters. The stock albumin solution was kept in the icebox as the standard. Thymol was added as the preservative. In order to standardize a batch of pooled sera, the standard albumin solution was further diluted quantitatively to the following concentrations expressed in micrograms of albumin nitrogen per milliliter: 2.95, 5.90, 7.37, 8.84, 10.32, 11.79, 14.74, 17.69, 20.64, and 29.48. Two milliliters of each of these albumin solutions were added to a series of Klett-Summerson tubes containing 1.0 ml. of 0.85 per cent saline solution. Two milliliters of the rabbit immune serum were then added to all the tubes. The reaction was allowed to proceed at room temperature for at least thirty minutes, and the turbidity of the immune precipitates* was measured at a wave length of 420 millimicrons. A solution containing 2.0 ml. of the antiserum and 3.0 ml. of 0.85 per cent NaCl solution was used as a blank. Under these experimental conditions the antibody in the antiserum was present in such a large excess that the immune precipitate did not flocculate as large aggregates. A uniform suspension with constant and reproducible turbidity readings was obtained by gentle stirring. The turbidity readings which reached a maximum within thirty minutes were then plotted against the micrograms of human albumin nitrogen added, Fig. 1.

Determination of Albumin in Human Serum or Plasma—One half milliliter of human serum or plasma was diluted to 100 ml. with 0.85 per cent sodium chloride solution, and this solution was used for the determination of the total nitrogen by the micro-Kjeldahl method† and for the determination of albumin concentration. One milliliter of this solution was pipetted into two Klett-Summerson tubes each containing 2.0 ml. of 0.85 per cent sodium chloride solution for duplicate determinations. Two milliliters of the standardized antiserum were added to each tube. The contents in the tubes were allowed to stand at room temperature for thirty minutes or longer, and the turbidity was measured with a Klett-Summerson photoelectric colorimeter against a control tube containing 2.0 ml. of antiserum and 3.0 ml. of the saline solution. This procedure permits a technician to complete at least fifty albumin determinations in one working day.

*If hemolyzed antihuman albumin serum was used the immune precipitate was centrifuged for ten minutes and the supernatant was removed by suction with a fine capillary attached to a vacuum, care being taken not to remove any immune precipitate. Then 5.0 ml. of a normal saline solution were added to suspend the immune precipitates and the turbidity readings were measured.

†Since we have accumulated our data, it has been found equally accurate to determine the total protein concentration by measuring the turbidity produced by 2.0 ml. of the diluted serum (1.00) and 3.0 ml. of 5 per cent trichloroacetic acid solution. The turbidity of the trichloroacetic acid precipitate bears a quantitative relationship with the total protein nitrogen determined by the Kjeldahl method.

Calculation—The per cent of the total nitrogen in the sample present as albumin nitrogen (see Table I) was calculated as follows. One can estimate the amount of human albumin (C) corresponding to the turbidity readings (B) from the standard curve (Fig 1). Multiplying C by the serum dilution (A)

Fig 1—The relationship between the turbidity of immune precipitate and the amount of human albumin nitrogen added to 2.0 ml of its homologous antiserum

gives the total albumin nitrogen present per milliliter of the original sample (D). The ratio of D to the total nitrogen in milligrams per milliliter of the original serum (E) as determined by the Kjeldahl method or in terms of the turbidity of the trichloroacetic acid precipitate, multiplied by 100, is the per cent

TABLE I THE CALCULATION OF HUMAN ALBUMIN CONCENTRATION FROM THE TURBIDITY READINGS

of total nitrogen as albumin nitrogen. The results of the calculation of three samples of sera containing different percentages of albumin are given in Table I for illustration.

RESULTS

The results of the analysis for human serum plasma albumin by different methods are presented in Table II. The data are arranged according to the total number of analyses expressed in per cent which agreed within certain limits with the electrophoretic analyses. They demonstrate that over half (58 per cent) of the samples analyzed by the immunologic method agreed within

TABLE II RESULTS OF THE DETERMINATION OF HUMAN ALBUMIN BY DIFFERENT METHODS ARRANGED ACCORDING TO THE DEVIATIONS FROM THE ELECTROPHORETIC ANALYSIS (TAKEN AS 100 PER CENT)

In the calculation of agreement the figures obtained for albumin by the electrophoretic analysis were assumed to be 100 per cent. The analyses were done in Veronal or Veronal citrate buffer of ionic strength 0.10 and pH 8.6.

†The Howe method¹ as modified by Robinson and co-workers was used.

‡The precipitation and filtration of the precipitates were performed in an ice bath at about 1°C.

10 per cent about three-fourths (76 per cent) agreed within 15 per cent and 91 per cent agreed within 20 per cent of the electrophoretic albumin. On the other hand, none of the results obtained by the salt fractionation method agreed within 15 per cent. 5 per cent of the samples agreed within 20 per cent and only 10 per cent agreed within 30 per cent of the electrophoretic albumin. Similarly, the distribution of the agreement between the electrophoretic and

the alcohol precipitation methods² was as follows 24 per cent of the analyses was within 10 per cent and 38 per cent was within 15 per cent of the electrophoretic albumin. The data therefore indicate that the routine determination of albumin by the immunologic method approaches the accuracy of the electrophoretic analysis. In the present comparative study the electrophoretic albumin was assumed to be correct and therefore assigned as 100 per cent. This assumption was not totally justified since several errors, as pointed out by Petermann and co-workers,⁷ are inherent in the electrophoretic technique. However the cumulative error may amount to only a few per cent.

The analytic results also were grouped according to the per cent of electrophoretic albumin present in the sera. Within each group the agreement between analysis by the electrophoretic and other methods is recorded (see Table III), the figures obtained by the former method were taken as 100 per cent. The data demonstrate that the immunologic results agreed within a few per cent of the electrophoretic albumin for sera ranging from 20 per cent (hypoalbuminemic sera) to 60 per cent (normal sera) of the total serum proteins. In other words, this method is applicable equally to severely hypoalbuminemic sera.

TABLE III COMPARISON OF ANALYTIC RESULTS OF HUMAN ALBUMIN IN SERA CONTAINING DIFFERENT AMOUNTS OF ELECTROPHORETIC ALBUMIN (TAKEN AS 100 PER CENT)

*Standard deviation

and to normal sera. On the other hand, the agreement between analysis by the electrophoretic and two other chemical methods appears to be best at a high percentage of albumin, and the discrepancy becomes larger as the per cent of albumin in the sera decreases. This situation can be explained on the basis that the so-called albumin obtained according to the fractionation methods contains not only albumin but also alpha globulins.⁸ The per cent of alpha globulins in hypoalbuminemic sera is generally much higher than that in normal sera.⁸

Application of the Precipitin Method—The chief advantages of the immunologic method over either the chemical or electrophoretic methods lie in the small quantity of albumin necessary for each determination and in the specificity of the method. These advantages make it possible to apply this method to the estimation of albumin in fluids of clinical interest. For example, we have followed the disappearance of albumin after an intravenous administration of 75 Gm. of human albumin to a patient with metastatic melanoma. The total circulating plasma protein, as well as the total circulating albumin, was determined shortly before and at various times after injection. The results, given in

*According to our experience it was essential to use freshly obtained serum samples for the determination with the methanol method; otherwise the results are erratic and may be off as much as 100 per cent or more. The method may be satisfactory in the hands of research chemists but is difficult to control adequately in a clinical laboratory.

Table IV, show that the injection of albumin brought about (1) an increase in total circulating plasma proteins from 168 to 217 Gm. an increase of 49 Gm., and (2) an increase of albumin from 98 to 163 Gm. an increase of 65 grams. The percentage of albumin was raised from 58 to 75 per cent. These effects were demonstrable on the 3½ hour samples. However twenty four hours after injection the total plasma proteins but not the albumin dropped to the preinjection level, thus the per cent of albumin in the total serum proteins remained practically unchanged. When these studies were extended to other types of

T C A Total circulating albumin

For the calculation of proteins in circulation the plasma clots were determined by the method of Gregersen

cases the rates of disappearance of albumin were found to vary from one patient to another. It is to be emphasized therefore that the data presented in Table IV serve only to illustrate the usefulness of the precipitin method and not to demonstrate the rapid disappearance of albumin following albumin transfusion.

Other applications of the immunologic method may include the estimation of the albumin in the urine of nephrotic patients and the determination of albumin in the cerebrospinal fluid. The possible diagnostic significance of the latter determination was pointed out in the preliminary note of Kabat⁹ and associates.

DISCUSSION

In this communication we have presented the analytic data obtained by several methods for the determination of human albumin in serum or plasma. Like other investigators, we found that the salt fractionation procedure gave the least reliable results, particularly with plasma from hypoalbuminemic patients and that the methanol method is an improvement over the salt fractionation procedure. However, Boek¹⁰ concluded from his study that the ammonium sulfate method yielded essentially the same results as the alcohol method. The immunologic method was found to yield results which agreed well with the electrophoretic albumin, regardless of its concentration. Besides being accurate and fast, the immunologic method requires much less material for each test and therefore permits the estimation of albumin in such physiologic fluids as spinal fluid and urine.

In a preliminary note, Kabat⁹ and collaborators reported an immunochemical estimation of albumin. Their procedure was very similar to that published by one of us³ except that the quantity of immune precipitate was measured by Kjeldahl analysis instead of by turbidity. We found that the turbidity method

is not only rapid and time saving but also gives results which are sufficiently accurate for a clinical method. It avoids the separation of the immune protein from the other proteins in the sera and the preliminary washings which are required by the Kjeldahl determinations.

SUMMARY

The results of routine estimation of human albumin by different methods were compared. It was found that the immunologic method appeared to be superior to the chemical methods and gave reliable results with sera containing different amounts of albumin. Because of the minute quantity of albumin required for each analysis and the specificity of the test, the immunologic method also has been found useful to estimate the excretion of albumin in the urine of nephrotic patients and to determine the amount of albumin in the spinal fluid.⁹

SANITIFIC DIETS

THEIR USE AS A DIAGNOSTIC PROCEDURE IN ALLERGIC DISEASE

PETER ROWE M.D. * AND JOHN M. SHILDON M.D.†

ANN ARBOR, MICH.

INTRODUCTION

THE evaluation of the role of ingested foods in the production of allergic symptoms is difficult and present methods of approach are frequently unsatisfactory. It is well established that the usual cutaneous and intracutaneous tests with food allergens are of little practical value in this regard for it is generally agreed that positive skin tests do not necessarily indicate clinical sensitivity.¹ It is equally apparent that opinion regarding the incidence and importance of foods as allergens varies widely.²⁻⁴

One of the basic principles used both in the diagnosis and treatment of allergic disease is that removal of the patient from the offending allergen is followed by remission of the symptoms which resulted from the exposure to that allergen. Therefore if the symptoms of which any patient complains are due primarily to ingested allergens and if said patient can be maintained on an intake free of offending agents the symptoms should disappear. This thesis is the basis for the use of most rotational and elimination diets. Furthermore, if patients could be maintained upon a nutrient preparation to which they could not become sensitized the question as to whether or not food factors are important etiologically in the production of symptoms in any given case could be answered finally and decisively in a short time. In an effort to take advantage of these principles various nutrient preparations of low allergenic potential have been used previously. Hill⁵ used Amigen in combination with Dextrimaltose, olive oil, arrowroot, starch, brewers' yeast and various minerals as a substitute food for milk sensitive infants with eczema. The proteins and amino acids were assumed to be nonallergenic and the author noted that the preparation was negative upon skin test in patients with a positive skin reaction for casein. In thirty-six patients to whom this preparation was given nineteen had a satisfactory result that is the food was well taken, the eczema improved and there was weight gain. In nine patients the procedure was unsatisfactory and in the remaining cases results were inconclusive. Hampton⁶ used a similar preparation for two patients with purpura and obtained relief of symptoms in both. Olmsted, Harford and Hampton¹⁸ reported the use of an enzymatic casein digest in combination with a fat (corn, olive or cottonseed oil), dextrose, minerals and gelatin for nine patients with various allergic disorders. After a seven day

†Associate Professor

trial of the diet, they included or excluded foods as etiological factors in the production of symptoms. Glynn¹⁰ mentioned the use of protein hydrolysates in infants with severe eczema, and stated that 50 per cent of his patients improved.

With such a background in mind, numerous patients have been maintained on synthetic diets at the University Hospital in an effort to evaluate more definitely the role of ingested allergens in the production of allergic symptoms.

METHOD OF STUDY

Several formulas were used in the study of the cases which will be enumerated below. The first preparation used was Amigen, the pancreatic hydrolysate of casein, 77 per cent of which was in the form of simple amino acids and 23 per cent as short chain polypeptides. Pork or sheep pancreas was used for the enzymatic digestion. All of the known essential amino acids were present in the product, 150 Gm of which contained two thirds of the daily mineral requirement except for magnesium and potassium. A great volume of work has been done on the oral and parenteral administration of Amigen and other protein hydrolysates. It appears to have been established that Amigen will not sensitize laboratory animals to subsequent injections of skimmed milk, pancreatic extract, or Amigen itself,^{9, 18, 27} that protein hydrolysates are absorbed from the gastrointestinal tract following oral administration,²⁸ and that excess amounts of nitrogen are not recovered from either urine or stool following oral or parenteral administration.^{2, 11}

Amigen was prepared for serving by dissolving 100 Gm of the powder in 1 liter of hot water to which 225 Gm of cane sugar were added. This was served over cracked ice in four equal portions at regular intervals throughout the day. The mixture contained 1,200 calories and the equivalent of 75 Gm of protein. A greater quantity was occasionally used if it was thought advisable to keep the intake at higher caloric level. Some patients preferred Amigen and water without added sugar. In these instances the specified amount of carbohydrate was eaten separately as desired during the course of the day. More recently, in some cases Protolysate* has been used in lieu of Amigen. The only essential differences between the two was that the enzymatic activity utilized in the production of Protolysate was derived from fish creca.²⁹

The second formula used contained Amigen in combination with Dextrinmaltose and olive oil†. A third preparation consisted of Amigen, dextrose, and certain synthetic vitamins‡. The general composition and caloric equivalents of each of these preparations have been compiled in Table I.

TABLE I

FORMULA	CONTENTS	PROTEIN (GM)	CARBO- HYDRATE (GM)	FATS (GM)	CALORIES PER LITER

*Mead Johnson & Company

†Mead-Johnson Laboratory Product #232 Dextrinmaltose 43.95 per cent, olive oil 18.10 per cent, Amigen 20 per cent, starch 10.39 per cent, calcium gluconate 3.64 per cent, other mineral salts and vitamins 3.32 per cent (monobasic potassium phosphate, dibasic potassium phosphate, calcium hydroxide, potassium chloride, magnesium oxide, thiamin, riboflavin, niacinamide).

‡Mead-Johnson Laboratory Product #211 dextrose 77.86 per cent, Amigen 18.99 per cent, other mineral salts and vitamins 3.15 per cent (sodium chloride, calcium carbonate, dibasic calcium phosphate, dibasic potassium phosphate, ferrous sulfate, thiamin, riboflavin, ascorbic acid, citric acid).

All patients had a complete study which included history, general physical examination and routine laboratory work (serology, chest x-ray, urinalysis, complete blood count). An allergic survey followed which included an allergic history, complete cutaneous and intracutaneous skin tests in most cases, and other studies (vitamin therapy, cytology of exudates) if indicated. Before starting a patient on a trial of synthetic diet the possibility of allergic symptoms arising from causes other than ingesta was excluded insofar as possible by the following practices:

- (1) A period of adjustment in the hospital (four to six days) was completed to permit clearing of any symptoms which might have been the result of environmental factors.
- (2) An antidiarrhea plan was instituted in forty of the fifty-one cases. Among the other patients there was neither clinical story nor positive skin test to suggest dust sensitivity, and symptoms were those most unusually due to food allergy.
- (3) Acute or chronic, active respiratory infection if present was treated by chemotherapy and/or antibiotics until maximal response was obtained.
- (4) Pollen sensitive patients were not evaluated on synthetic diets during the specific pollen season.

Finally two other precautions were observed in the effort to minimize interference with the trial of diet:

- (1) Symptomatic management was simplified as much as possible so that the result of diet could be more readily evaluated. For instance effort was made to control asthma with but one symptomatic drug, so that the number of drugs required did not serve as a convenient measure of response.
- (2) Collateral therapy was eliminated during this period if possible. This was frequently difficult particularly in the case of diffuse cutaneous disease.

If the program of synthetic diet was initiated patients were managed thereafter as follows. Diet was continued for a period of ten days as a general rule. If there was definite remission of symptoms before the ten days had elapsed sometimes the course was shortened. If there was equivocal response at the end of ten days the diet occasionally was continued for a longer time. If there was no symptomatic response whatsoever in the ten days time, dietary management of the patient was abandoned and food allergy was considered a most unlikely etiology for the patient's complaints.

When patients showed a definite remission of symptoms upon the synthetic diet one of two courses was followed. Single food additions could be made at three or four day intervals if the purpose was to identify single allergens. In such cases foods held in clinical suspect were added initially. If, however, the patient's clinical condition necessitated more rapid return to an adequate natural diet, food additions were multiple, in groups of two to four, and foods thought to be innocuous were added first. Factors which conditioned this decision were the clinical condition of the patient, the severity of prior symptomatology, and the advisability of precipitating it.

CASE SELECTION

All patients selected for trial of diet in this study were experiencing daily symptoms of an incapacitating nature. They all had been surveyed as previously described and if symptoms persisted which were thought possibly to be allergic in origin synthetic formulas were advised to aid in the evaluation of the role of ingesta in the production of their symptoms. Thus in many instances the program was used because inhalant and drug allergens had been reasonably excluded and symptoms had persisted. Despite case selection by a method which had few positive criteria the number of patients for whom the program was advised did not increase rapidly. In 1946-1947 over an eighteen month period there were but fifty-one such instances. Final diagnoses in these cases have been tabulated in Table II.

TABLE II

Perennial rhinitis	1

Ulcerative stomatitis	1
Periarteritis nodosa	1
Disseminated lupus†	1
Total	51

*Admitting diagnosis was bronchial asthma

†Discharge diagnosis uncertain disseminated lupus considered the most likely Biopsy not conclusive

Multiple diagnoses were the rule in most cases, reflecting the well known tendency for allergic disease to affect more than one organ system, but the predominating symptom-complex was used for the purpose of the classification in Table II. It should be emphasized that of the fifty-one patients put on the synthetic diets, forty-eight were hospitalized.

OBSERVATIONS

No diagnostic or therapeutic measure is of general value, however accurate or beneficial it may be, unless it can be applied readily to most patients for whom it may be indicated. It must, therefore, be admitted that these formulas were almost uniformly distasteful to patients, and those on synthetic diet programs required complete explanation initially and continued moral support throughout the trial period. In our experience, no one of these formulas was definitely more acceptable than any one of the others. However, against the initial objection on the part of most patients stands the fact that of the fifty-one to whom the diet was offered, all but three attempted the trial. Of the three patients refusing to continue the program after their initial meal, one had a vague cephalalgia later diagnosed as a functional problem by the psychiatric consultant, one had an eczema eventually diagnosed as neurodermatitis by the dermatologist, and one had bronchial asthma of moderate severity.

Four other patients developed nausea, vomiting, and/or diarrhea during the course of the trial period which necessitated interruption of the program. All four of these patients developed their symptoms on, or slightly before, the seventh day. In the records of nine other patients there was note of slight nausea and vomiting, the occasional refusal of a feeding, or mild diarrhea. The program was completed in all the latter instances.

A second general aspect of the situation to which attention had to be directed was the over-all effect of these formulas upon the patients. Elimination and rotational dieting have been rightfully criticized by some because they

use frequently leads to inadequate intakes and depleted nutritional states. Since the trial period was a short one, after completion of which effort was made to restore an adequate, balanced intake to the patient it was not felt that the trial would precipitate deficiency states. Caloric intake was kept at 1,200 calories or above. In thirty-eight instances where there was adequate and accurate record of body weight, twenty-six patients lost an average of 42 pounds each, five patients gained an average of 21 pounds each and in seven instances there was no change in body weight. In no instance was there any clinically demonstrable detrimental effect upon the patients other than the gastrointestinal symptoms noted. These symptoms quickly subsided upon termination of the diet.

Considerable difficulty was experienced in evaluating the specific result of trial of diet upon allergic manifestations. Despite the fact that the plan appeared to lend itself to precision in this respect and to the development of objective criteria for making such decisions changes were frequently relative and subjective responses had to be taken into consideration. Responses to diet trial, however, could be grouped into the following four categories:

(1) Patients in whom there appeared to be no food factor. These patients completed ten days of diet without change in their symptoms.

(2) Instances in which there appeared to be a definite food factor. Symptoms of these patients cleared while on synthetic diet and were reproduced by additions to the formula.

(a) If additions were simple and flare resulted single allergens were identified.

(b) If groups of foods were added with resultant flare a definite food factor was considered present, even though a specific allergen was not identified.

(3) A small group of patients who experienced complete remission of symptoms upon the diet, but who subsequently tolerated return to general diet without reappearance of symptoms.

(4) Instances in which trial of diet was unsatisfactory for one of the following reasons:

(a) Failure to complete the course

(b) Uncontrolled collateral therapy

(c) Equivocal result

(d) Inadequate follow up contact with patient

Table III summarizes the results in fifty-one patients who received synthetic diets.

In Group 1 foods were presumptively eliminated as a cause of symptoms. The fifteen patients in Group 2 had a definite food factor. It follows therefore that in thirty-eight instances information of benefit to both patient and physician was obtained.

In the group of fifteen patients in whom there was thought to be a definite food factor twenty-three separate allergens were diagnosed. Milk was the most frequent offender (eleven times), wheat, white potato and

beef were next (each three times). Not all patients in this group had been skin tested, but the majority had. For fifteen of the twenty three allergens demonstrated, there were both scratch and intracutaneous tests for comparison. In but four of the fifteen instances were there positive tests, either scratch (one) or intracutaneous (three), of *any* degree of positivity. This lack of correlation between skin testing and clinical observation in food allergy is in accord with general opinion as to the diagnostic specificity of skin testing for food allergens.¹⁴

DISCUSSION

Several considerations relative to the foregoing should be discussed in somewhat greater detail. First, the nonallergenicity of the formulas used cannot be assumed. The possibility remains that milk-, fish-, pork, mutton, or corn sensitive patients might continue to have allergic symptoms secondary to the ingestion of minute amounts of these substances remaining unaltered and undetectable in the final product. In view of the presence of short chain polypeptides, there remains the potential danger of immunologic reaction.⁶ An enzymatic casein digest will not sensitize laboratory animals,^{9, 18,} and clinical observations supporting the theoretic nonallergenicity of these preparations have been made. For instance symptoms of patients known to be milk sensitive have been observed to clear upon an enzymatic digest of casein, and later to flare with the addition of milk to the basic formula. The final answer to this question should be withheld pending further chemical investigation and trial.

It should be re-emphasized that unpalatability is the chief objection encountered in the use of these diets. Our results have not been tabulated for each of the formulas because practical differences between them with respect to acceptability or clinical result were not apparent. It seems doubtful that any patient with less than major allergic symptoms would elect to remain upon such a program for the full trial period. Because of this impression, the procedure almost uniformly was reserved for inpatients.

The importance of controlling environmental factors the dust allergen and concomitant infection prior to embarking upon a diagnostic dietary regime cannot be overemphasized. On several occasions it was observed that proper consideration of these factors obviated the necessity for dietary trial which had originally been contemplated. The presence of an active infectious process, at least in the respiratory tree contraindicates a trial of one of the synthetic formulas. For example one patient with bronchiectasis superimposed on an allergic asthma could not be controlled from the standpoint of the asthma by any means during a flare of the pulmonary infection. After control of the pneumonitis with antibiotics and postural drainage residual asthma cleared rapidly upon institution of a synthetic diet.

It again should be pointed out that patients for whom diet trial was ordered were those whose symptoms were more than moderately incapacitating. The total number forms but a small though unbiased percentage of the cases seen in Allergy Clinic.

The cause of gastrointestinal symptoms secondary to the use of these formulas is somewhat obscure. Aspartic and glutamic acid are reported to cause nausea and vomiting in both man and laboratory animals^{1,2} and casein hydrolysates contain both of these amino acids. This may explain the development of symptoms but delay in their appearance until the sixth or seventh day of dieting is less readily explained on this basis than if appearance was more immediate. One patient who developed nausea and vomiting with Amigen orally was maintained satisfactorily on intravenous Amigen and subsequently tolerated a second trial of the oral preparation for a ten day period without the development of gastrointestinal tract symptoms. Although this patient was sustained with the parenteral preparation when unable to tolerate Amigen orally it was not the general policy to follow this plan. The end did not appear to justify the means even in the face of considerable literature attesting to the safety and efficacy of parenteral amino acid administration.^{1, 8, 10, 12, 13, 17, 19, 20, 21, 4}

Finally it should be kept in mind that the trial of diet occasionally was used as a differential diagnostic procedure in syndromes of obscure etiology. The final diagnosis was in some cases a condition not commonly thought to be of allergic origin. These cases have been included irrespective of this consideration because they represented instances in which synthetic diets were utilized in differential diagnosis. The recorded results (Table III) usually reflected the accepted nonallergic etiology of the disorder (namely pulmonary emphysema bronchiectasis) but in two instances (lupus erythematosus periarthritis nodosa) there was apparent benefit from the formulas in disease entities not commonly held to be allergic in origin. The patient with lupus erythematosus was a middle aged white man who was the victim of a disseminated process affecting most of the major organ system. A skin biopsy was reported as compatible with lupus but a skin muscle biopsy from a different site revealed essentially normal tissues. The clinical impression at the time of discharge was probable lupus erythematosus and follow up contact with the patient was insufficient to verify or disprove the diagnosis. The

symptoms of this individual twice cleared upon synthetic diets and twice flared with additions. Periaenteritis nodosa occurred in a middle aged, white woman. The diagnosis was made at the time of necropsy. Prior to death the patient had had almost intractable asthma for many months. There was associated high grade (20 to 50 per cent) eosinophilia observed in peripheral blood as well as transient pulmonary consolidations which appeared serially in different locations in the lung parenchyma. These were clearly demonstrated by successive chest x-rays. In the last six months of life, the only time of relative freedom from asthma were those periods when the patient subsisted upon synthetic formulas only. The example of this latter patient may be suggestive evidence of an allergic etiology for periaenteritis nodosa, supporting Rich's recent observations.³⁰ The instance of probable lupus erythematosus can be regarded as nothing more than a recital of observations which at this time cannot be extended to any conclusions.

In comparison with previously reported use of synthetic diets the formulas discussed herein would appear to be potentially less allergenic than any of the others. A more varied and larger series of cases has been reviewed than previously.

CONCLUSIONS

A group of fifty-one patients suffering from various ailments thought to be entirely or in part, of allergic origin has been studied by means of synthetic diets. In thirty-eight of these patients, or 74 per cent, it was felt that the trial afforded information of definite positive benefit to both the patient and physician information which could not have been acquired by other methods in so short a time with equal clarity.

The method would seem to supply another worth-while, safe, and sound approach to the problem of exact diagnosis of food allergy, although at the moment, in its present form, it does not appear practicable for outpatient use or for use upon patients with less severe allergic manifestations.

Until more clinical experience and study have justified the assumption that these formulas are nonallergenic, positive diagnoses of food allergy may be more valid than the negation of its presence after trial of synthetic diet.

The authors wish to acknowledge their appreciation of the work of Miss Ann Remer, Therapeutic Dietitian, University Hospital in the planning, preparation, and supervision of the serving of the synthetic formulas discussed herein.

THE LIFE SPAN OF THE MEGALOCYTE AND THE HEMOLYTIC SYNDROME OF PERNICIOUS ANEMIA

KARL SINGER, M D, JOSEPH C KING, M D, AND SIDNEY ROBIN, M D
CHICAGO, ILL

THERE is now general agreement that pernicious anemia is a deficiency disease. The ability of the liver extract principle to change the megaloblastic maturation arrest to a normoblastic type of red cell production seems to demonstrate that the site of the primary action of the antipernicious factor is located in the marrow.

Patients with Addisonian anemia also show regularly a severe disturbance of the pigment metabolism. There is usually mild retention jaundice. The hemolytic index,¹ that is, the urobilinogen excretion in the feces correlated with the total mass of circulating hemoglobin, is far in excess of normal values.²

These abnormalities of the pigment metabolism apparently are indicative of an existing hemolytic process since they also are observed in all other known hemolytic syndromes. However, contrary to these other types of hemolytic disorders, untreated cases of pernicious anemia show no increase or only a very slight increase of the reticulocytes in the circulating blood.³ If reticulocytosis is evaluated as a measurement of red cell replacement and the high pigment output as an indication of the simultaneously existing increased erythrocyte disintegration, a considerable imbalance in favor of erythrocyte destruction would be present in untreated pernicious anemia. Consequently the peripheral blood should become rapidly depleted of erythrocytes, resulting in an early death of the patient. Clinical observations are not in agreement with such a mechanism. Therefore Addisonian anemia often has been considered not to be a true hemolytic syndrome. In order to account for the excessive bile pigment output, various explanations have been suggested. It has been postulated either that hemoglobin is destroyed in the marrow without ever entering the circulation,⁴ or that the excessive urobilinogen is not derived from hemoglobin at all but represents rather pigment formed from other substances.⁵ All these hypotheses tacitly imply that the morphologically abnormal megalocytes, after having reached the circulation, have then a normal survival time.³

In previous publications^{6,7} it has been pointed out that the common denominator of all hemolytic syndromes regardless of the great variety of causative mechanisms is to be found in a shortened life span of the various types of cells involved. In order to determine whether Addisonian anemia may be classified as a true hemolytic syndrome, estimations of the survival time of erythrocytes from patients with untreated pernicious anemia were performed in this study.

MATERIAL AND METHODS

The diagnosis of pernicious anemia in patients used in this investigation was based on a compatible clinical picture with histamine refractory achlorhydria, the presence of a macrocytic hyperchromic anemia, and a marrow examination showing the megaloblastic type of erythrocyte maturation accompanied by giant metamyelocytes. A moderate hyperbilirubinemia was found in the untreated patients. Furthermore, all patients responded well to liver treatment.

Fig. 1—survival time of normal red cells in artificial erythrocytosis expressed in per cent of surviving cells

The methods used in this study have been described in detail in a previous publication. Determinations of the survival time were performed with the method of differential agglutination (Alby technique). Only young normal children (2 to 4 years old) were elected as recipients. Because of their small circulating blood volume a correspondingly small transfusion was found sufficient to result in a satisfactorily high addition of the donor's cells per cubic millimeter. Packed cells derived from 250 to 500 cc of whole blood were introduced, yielding an initial increase of 340,000 to 820,000 red blood cells in the recipient's total erythrocyte level. The initial values were established twenty-four to forty-eight hours after transfusion in order to avoid any significant inaccuracy due to an augmentation of the circulating fluid volume although it is realized that some of the transfused cells already may have been eliminated within the first twenty-four to forty-eight hours. After determining the starting point follow-up studies were done twice weekly during the first month and from then on once every week.

Some of the recipients showed values of 5.5 to 5.8 million red cells following transfusion. In order to ascertain whether such an abnormally high count may have an influence on the survival time of the tagged cells, normal erythrocytes were transfused into children to such an extent that the total red count was brought up to more than seven million per cubic millimeter. Such an artificial erythrocytosis has no influence on the survival time. Fig. 1 shows an experiment in which the red count had been increased from an initial level of 5.8 to 7.7 million per cubic millimeter. After all transfused cells had disappeared the patient's red count was 5.5 million per cubic millimeter. The elimination curve of the foreign cell was a normal one and their average life span was 127 days, an entirely normal value.

RESULTS

Nowadays the scarcity of untreated cases of pernicious anemia presents a major obstacle to investigations on the pathogenic mechanisms operating in this disorder. Our study was performed on four cases only*. The hematologic data of the donors and also of the healthy recipients are compiled in Table I

Fig. 2—Survival time of pernicious anemia cells in normal environment expressed in per cent of surviving cells

Fig. 2 shows the curves illustrating the disappearance of the donor's cells. The percentages of the surviving cells are plotted against the number of days following transfusion. Patients 1 and 2 were patients with pernicious anemia in relapse who had received no specific treatment for several months prior to the experiment. Their red cells were completely eliminated within twenty-eight and seventy-five days respectively when transfused into a normal environment. The profiles of their elimination curves are definitely abnormal and are similar to those seen in the other hemolytic syndromes caused by an intracorporeal abnormality of the red cells.

Patient 3 had been under continuous treatment with liver for thirteen years. Then treatment was stopped entirely for about three years. A severe degree

*Normalized blood picture after extensive liver treatment

*We are indebted to Dr. S. Portis, Dr. L. Rappolt, and Dr. S. O. Schwartz for permission to use their patients in this investigation.

of anemia developed and the patient was advised to enter the hospital. A few days prior to admission he took some liver pills. On the day of admission hemoglobin was 6.8 Gm (44 per cent) red count 1.66 million and reticulocyte count 3.8 per cent. The reticulocytes increased to 9 per cent on the third hospital day and then came back to values below 1 per cent on the tenth day. There was also a slight rise of the hemoglobin and red cell count to 8.7 Gm (56 per cent) and 2.11 million respectively. At the time blood was taken for the determination of the survival time, the hemoglobin had decreased to 8.0 Gm (51 per cent) and the red count to 1.85 million. Since the antipernicious anemia principle changes the abnormal megaloblastic maturation back to a normal development of the red cells, one may assume that two different populations of erythrocytes existed in the blood of this patient at the time of the transfusion, namely red cells manufactured with the participation of the liver principle and also typical megalocytes produced in the absence of the erythropoietic factor. As can be seen from Curve 3 (Fig. 2) visualizing the elimination of the foreign cells, 66 per cent of the transfused erythrocytes disappeared within thirty days, the remaining 32 per cent were completely eliminated after seventy-two days. The profile of the curve showing a distinct biphasic character is also in agreement with the assumption of the presence of two different populations of erythrocytes in the blood of this insufficiently treated patient. The suboptimal doses of antipernicious principle may also account for the total shortened survival time observed in this particular case.

Patient 4 had a normalized blood picture because of continuous liver treatment for many years. The average survival time was 119 days, an entirely normal value. This is in agreement with the recent findings of Mollison⁸ who also demonstrated a normal survival pattern of red cells obtained from adequately treated patients with pernicious anemia.

Our results, therefore, demonstrate that in untreated cases of pernicious anemia there is a shortened survival time and an abnormal elimination pattern which becomes normalized after adequate administration of liver extract.

DISCUSSION

Determinations of the average life span of normal erythrocytes transfused into patients with pernicious anemia were performed by Ashby⁹ and also by

CELLS INTO NORMAL RECIPIENTS

RECIPIENTS						RESULTS

Wearn and co-workers¹⁰ as far back as 1921. A normal survival time of these transfused erythrocytes was found to be present. Recently Mollison⁸ has confirmed these observations by means of the most refined modern techniques. Therefore an extracorporeal mechanism damaging all circulating erythrocytes at random and thus influencing the life span is not demonstrable in pernicious anemia.

The survival time of the megalocytes (pernicious anemia erythrocytes) was determined with the Ashby technique by Wearn and associates (in 1922) who transfused these abnormal red cells into another patient with pernicious anemia. No abnormal behavior of the transfused corpuscles was found in this single instance. Morawitz¹¹ transfused normal red cells into a patient with severe pernicious anemia to such an extent that the majority of all the erythrocytes in the patient's circulation belonged to the donor's group. Since the anemia improved for a longer period of time but no change occurred in the greatly increased pigment output in the feces, Morawitz concluded that the transfused normal erythrocytes survived much longer than the pathologic megalocytes.

In 1945 one of us⁶ classified pernicious anemia as a true hemolytic syndrome caused by the presence of an intracorporeal anomaly of the erythrocyte. It was emphasized that hemolytic syndromes are not always produced by an erytholytic activity (immune bodies, hypersplenism) but that structurally defective erythrocytes, when exposed to the normal means of destruction, disintegrate much more rapidly than normal red cells. By using the method of cross determination of the survival time of the red cells,^{6,7} it is possible to distinguish in any given case whether an extra- or an intracorporeal mechanism is involved. When normal erythrocytes, transfused into a recipient with a hemolytic syndrome, survive normally, whereas the patient's own red cells, transfused into a normal person, have a considerably shortened life span, an intracorporeal abnormality may be suspected. Conversely, when normal red cells, transfused into the patient with the hemolytic syndrome, are as rapidly destroyed as the patient's own cells, the presence of an extracorporeal mechanism may be assumed.

While this study was in progress, we came across a report of Loutit¹ to the Royal Society of Medicine stating that he had transfused erythrocytes from two patients with untreated pernicious anemia into normal recipients and had observed a survival time of thirty and sixty days respectively. This is quite in accordance with our observations reported in the present paper. Although the elimination curves of Loutit's and our cases are all definitely abnormal, there is a considerably wide range of the average life span which is probably explained by the individual variability of the available antipernicious principle for the manufacturing of the cells.

The demonstration of an abnormal life span of the megalocyte characterizes Addisonian anemia as a true hemolytic syndrome since the common denominator of all hemolytic disorders regardless of the great variety of causative mechanisms has been found to be a shortened life span of the various types of cells involved.

Although the shortened survival time undoubtedly accounts for an increased pigment production, the question arises whether it offers a truly satisfactory explanation for the excessively high output of bile pigment regularly observed in untreated cases of pernicious anemia.

The abnormalities of the pigment metabolism existing in this disorder have always been difficult to interpret. Watson⁷ in his extensive review has critically discussed this problem. Whereas in the other hemolytic syndromes there is a high reticulocyte count indicating considerable red cell replacement, untreated cases of pernicious anemia show no increase or only a very slight increase of the reticulocytes in the circulating blood. Whipple was the first to point out the great discrepancy between apparent blood regeneration and destruction in untreated pernicious anemia and he expressed his doubt that the increased pigment excretion represents increased hemoglobin destruction. He postulated that the excessive urobilinogen is mostly derived not from the hemoglobin of the circulating red cells but rather from an increase of a hypothetical 'pigment complex'. This pigment complex was considered to originate from hemoglobin derivatives, food products and body proteins. Jedlicki⁸ assumed that the elevated bile pigment output stems from hemoglobin only which however, is predominantly destroyed in the marrow. Both hypotheses have tacitly implied that the morphologically abnormal megalocytes after having reached the circulation have then a normal survival time.

Fig. 3 visualizes the hypothetical relationship between the interdependent factors involved in maintaining the erythrocyte level⁹ (A) under physiologic conditions, (B) in the common hemolytic syndromes (for instance hemolytic jaundice, sickle cell anemia), and (C) in pernicious anemia according to the theories mentioned.

It should be emphasized however that Heilmeyer¹³ and many other investigators (Lit. see Watson⁸) have rejected these hypotheses and maintained that the excessive urobilinogen output could be adequately explained on the basis of an increased hemoglobin destruction particularly if the extreme hyperplasia of the marrow which exists in pernicious anemia is taken into account.

At first glance the demonstration of a shortened survival time of the megalocytes seems to make any special hypotheses concerning the increased pigment output superfluous. However recent investigations¹⁴ demonstrate that the whole problem is much more complicated. Shemin and Rittenberg¹⁵ showed in 1946 that oral feeding of glycine labeled with N¹⁵ results in the incorporation of N¹⁵ in the heme molecule of the red blood cells. The labeled porphyrin remains in the erythrocytes until these cells disintegrate and is then transformed into stercobilinogen. By means of this technique the same figure for the average life span of normal erythrocytes was obtained as previously determined with the method of differential agglutination. However when labeled stercobilin was isolated from the feces and its amount correlated with the rate of erythrocyte disintegration it was found that a significant portion of the normal pigment production is apparently derived from sources other than hemoglobin.¹⁴ In one case of untreated pernicious anemia a considerable increase of this extra

pigment was also demonstrable. Therefore these findings seem to support Whipple's hypothesis. Quite obviously an entire reinvestigation of the pigment metabolism in all the hemolytic syndromes now becomes necessary. However, the new evidence does not in any way reflect upon our interpretation of the significance of the shortened survival time of the megalocytes.

Fig 3—Relationship of the interdependent factors maintaining erythrocyte level

The absence of any considerably increased reticulocyte count in untreated pernicious anemia is of particular interest. It must be assumed that in this disorder replacement of erythrocytes occurs predominantly by means of non reticulated megalocytes.¹⁶ Apparently completely matured although qualitatively abnormal corpuscles are released into the circulation. This is quite a distinguishing feature since no such abnormality of replacement is demonstrable in the other types of hemolytic anemia. There has been some speculation that the liver extract principle may contain a specific reticulocytogenic factor. Oliva and Frascarelli¹⁷ report that plasma obtained from patients with a high reticulocyte count caused a definite increase in reticulocytes when injected into normal persons. This was observed with blood from patients with pernicious anemia.

at the reticulocyte crises following liver treatment and also in patients with microcytic hypochromic anemia treated with iron. Oliva and Frascarelli suggest that in pernicious anemia this hypothetical reticulocytogenic factor acts in combination with the maturation principle. Somewhat against this assumption is the satisfactory hematologic response of patients with pernicious anemia treated with pteroylglutamic acid.

The demonstration that pernicious anemia is a true hemolytic syndrome does in no way invalidate the concept of this disorder as a deficiency disease. It is because of the absence of the maturation principle that defective erythrocytes enter the circulation and are then eliminated more rapidly than normal ones. Thus pernicious anemia is another example of a hemolytic syndrome caused by an intracorpuseular mechanism, namely a poorly constructed cytoskeleton of the erythrocytes.

SUMMARY

The red cells of patients with untreated pernicious anemia have a shortened survival time. After adequate treatment the life span of the erythrocyte becomes normal.

The demonstration of a shortened survival time of the megaloocyte permits the classification of pernicious anemia as a true hemolytic syndrome since the common denominator of all hemolytic anemias regardless of the great variety of causative mechanisms has been found to be a shortened life span of the various types of cells involved.

The significance of the finding of a shortened survival time for the explanation of the abnormal pigment metabolism in pernicious anemia is discussed.

Quite different from the other types of hemolytic anemia replacement of red cells seems to occur by means of nonreticulated erythrocytes.

The demonstration that pernicious anemia is a true hemolytic syndrome does in no way invalidate the concept that this disorder is a deficiency disease. It is because of the absence of the maturation principle that defective red cells enter the circulation and are then eliminated more rapidly than normal ones. Thus pernicious anemia is an example of a hemolytic syndrome caused by an intracorpuseular mechanism, namely a poorly constructed cytoskeleton of the erythrocytes.

THROMBOPENIC PURPURA THE FAILURE OF DIRECT BLOOD TRANSFUSION TO RAISE THE PLATELET LEVEL*

JOHN S LAWRENCE M D, WILLIAM N VALENTINE M D AND
WILLIAM S ADAMS M D
ROCHESTER N Y

IT IS the purpose of this report to show that the platelet level of patients with thrombopenia cannot be elevated significantly for any period of time by means of massive direct transfusions of blood. For a long time it has been our feeling as well as that of others, that blood transfusions do little in patients with thrombopenic purpura except to replace blood which has been lost by bleeding. However following blood transfusion in the amounts ordinarily used the dilution factor is so great that it has been impossible to determine accurately whether platelets in the transfused blood remain for any appreciable time in the circulation of the recipient.

Recently it was demonstrated in this laboratory that the circulating platelet level of the cat can be substantially raised for a period of a few days following cross circulation by way of carotid to carotid anastomoses with a normal animal.¹ The technique in effect, constituted a method of giving the thrombopenic recipient a massive direct blood transfusion through a continuous endothelial anastomosis. The experimental results made it seem pertinent to determine whether the platelet level in human subjects with very low platelet counts could be raised by massive direct transfusions of whole blood. On a priori grounds it seemed that massive direct transfusions should appreciably raise the platelet level and that if the blood platelet in man has a normal rate of utilization of the same general order of magnitude as that found in the cat this increased value should be demonstrable for a period as long as a few days. It was argued further that such an increase in the platelet level should have a favorable effect on hemostasis in thrombopenic individuals, and thus massive transfusions of whole blood would offer more benefit than the conventional indirect transfusion of 1 or 2 units of blood. Since the animal experiments had shown the life span of blood platelets to be much greater than that of the leucocytes under comparable conditions, it was hoped that thrombopenic purpura could be combatted by transfusions more effectively than agranulocytosis. Accordingly massive direct blood transfusions were given to two patients with marked thrombopenia.

The medical literature records only two pertinent publications of which we are aware. Duke¹ in 1910 reported that direct blood transfusion both raised the platelet counts and improved the hemostasis of three patients with thrombo-

penic purpura In one case a rise in platelet count of 120,000 per cubic millimeter was noted No data are given as to the method of direct transfusion employed or as to the amount of blood transfused Kiasso² in 1927 likewise recorded beneficial effects from blood transfusion in thrombopenic purpura In one case, following the transfusion of a single unit of blood, the platelet count rose from 11,000 to 114,000 per cubic millimeter one day following transfusion In the second case no significant elevation in platelet level occurred until six days after the transfusion of 450 cc of blood The amounts of blood transfused and the time intervals concerned are such that it seems unlikely that survival of transfused platelets could per se account for the observed elevations in the platelet counts

The failure of blood transfusion to replenish satisfactorily the circulating nonerythrocytic formed elements when these are dangerously low can be attributed to at least five possible causes (1) The life span of these elements may be so short that when transfused they rapidly disappear merely in the course of normal utilization This is true in the case of the white blood cells (2) The elements may be qualitatively or quantitatively altered within a short period in stored blood This factor is of undoubted importance (3) The transfused elements are rapidly dispersed in the comparatively large blood volume of the recipient and, in many instances, are diluted to the level of insignificance on this basis alone This is certainly true in instances where only 500 cc or less of blood are transfused (4) The abnormal state which prompted the transfusion initially may result in an abnormally rapid rate of disappearance of the transfused elements It is, of course, difficult to exclude this situation (5) The recipient may destroy the donor elements more rapidly than his own No satisfactory way of proving this exists

CASE 1—J J, a 37 year old Italian man, was first admitted to Strong Memorial Hospital in 1943 with complaints of dizziness, blurred vision, numbness and tingling of the left hand and left leg, and difficulty in walking There was generalized pallor of the right optic disc No objective sensory changes were observed There was some atavism in the finger to nose test with the left hand The blood Wassermann was negative The erythrocyte count was 5,820,000 per cubic millimeter, the hemoglobin was 15.8 Gm per cent, and the leucocyte count was 10,900 per cubic millimeter with a normal differential A diagnosis of multiple sclerosis was made and the patient was given a course of intravenous typhoid vaccine The patient was able to continue working and except for episodes of transient numbness the symptoms improved

In December 1945, the patient began to note pallor, exertional dyspnea, weakness, and fatigue He was admitted to the Rochester General Hospital where he was found to have a severe anemia Sternal marrow aspiration specimens suggested an aplastic bone marrow The patient received numerous blood transfusions with but transient benefit and was referred to Strong Memorial Hospital on April 2, 1946, for further study At the time of admission there were petechiae over most of the legs, and the patient's story indicated that a petechial rash had first appeared three months previously in the areas between the first and second fingers bilaterally The frequent occurrence of small hematomas had been noted for two months before admission There had been frequent free bleeding from the gums for two weeks prior to admission No history of ingestion of drugs of the type which are known to predispose to aplastic anemia could be elicited

On physical examination, with the exception of pallor of the optic discs the pertinent findings were limited to generalized pallor and the wide distribution of hemorrhagic mani-

festations There were petechiae on the tongue and the mucous membrane of the mouth oozing from the gums, clotted blood in the nostrils, and diffusely scattered petechiae over most of the body which assumed the proportion of hemorrhagic rash on the lower extremities The spleen was not palpable

At the time of admission the red blood cell count was 1,860,000 per cubic millimeter, the hemoglobin 12 Gm. per cent, and the leucocyte count 3050 per cubic millimeter with but 9 per cent granulocytes The urine showed 3 plus albumin and there was a positive test for blood The stool showed a 3 plus guaiac test for blood The clotting time (Lee White method) was 9 minutes and clot retraction was poor the clot being very friable and inelastic The bleeding time was in excess of 42 minutes The reticulocyte count was 18 per cent The platelets were virtually absent from the blood film A specimen of sternal marrow was removed surgically and a pathologic diagnosis of aplastic anemia was made Despite indirect blood transfusion and vitamin K, the clinical course was progressively downhill Continued bleeding was a troublesome problem and it was decided to attempt massive direct blood transfusion

On April 5 the patient's blood picture was as follows, prior to transfusion Erythrocytes 1,500,000 per cubic millimeter hemoglobin 4.8 Gm per cent volume of packed cell 130 per cent The platelet counts on three separate determinations (Rees Ecker method) were 4,000, 6,000, and 6,000 per cubic millimeter The blood film was almost completely devoid of platelets A direct transfusion of 690 cc was given and the patient developed a pyrogenic reaction necessitating discontinuation of the transfusion Three hours after the transfusion the platelet count was 0 per cubic millimeter on two determinations The following morning the erythrocyte count was 2,090,000 per cubic millimeter the hemoglobin 6.3 Gm per cent and the hematocrit, 17.0 per cent The platelet count was 2,000 per cubic millimeter In a two hour period 1,500 cc of whole blood were transfused by the multiple syringe method Despite this massive direct transfusion from normal donors the platelet count two hours afterward was but 6,000 per cubic millimeter and there was no discernible elevation in numbers of platelets on careful examination of the blood film Slow oozing of blood from the nose, present before the transfusion never abated The patient continued to bleed and died on April 13 No autopsy was performed

CASE 2—C. C., a 53 year old white man was admitted on Sept. 1, 1947 to the Eye Service complaining of a cataract of the right eye The history indicated a hemorrhagic diathesis dating back to childhood with recurrent episodes of petechiae and easy bruising covering a period of many years A splenectomy had been performed for idiopathic thrombopenic purpura in 1930 Following this there was only slight improvement in the bleeding tendency and the platelet count had remained depressed However in the year prior to admission there had been no significant episodes of bleeding

The patient had noted failing vision since 1929 when he was found to have cataracts In 1943 an iridencleisis had been performed following which the patient developed hemorrhagic glaucoma of the left eye Since that time he had been virtually blind in the left eye being able to discern only bright light and the vaguest outline of objects Vision in the right eye was becoming progressively smoky and the patient was threatened with nearly complete blindness Pertinent facts in the past history also included nephrolithiasis treated medically because of the bleeding tendency hernia at the site of the previous splenectomy and deafness of a mixed type in the right ear

On physical examination the lens of the right eye was cloudy white and vision was greatly reduced Vision was virtually absent in the left eye There were surgical scars in the left upper quadrant of the abdomen and there was slight bulging in this area when the patient strained There were a moderate number of scattered petechiae and a few larger purpuric areas Physical examination was otherwise essentially normal

The erythrocyte count was 5,700,000 per cubic millimeter the hemoglobin, 18.5 Gm per cent and the leucocyte count 10,850 per cubic millimeter with a normal differential formula The platelet counts were 20,000, 27,000 and 28,000 per cubic millimeter on three determinations The platelets were greatly reduced on the blood smear The bleeding time was 5½

minutes on one occasion and 11½ minutes on another. The clotting time was within normal limits and the clot retracted somewhat. The blood fibrinogen was 328 Gm per cent.

It was felt that removal of the cataract from the right eye was essential if the patient was to avoid blindness but that the hemorrhagic diathesis reduced materially the chances of successful operation. It was therefore decided to search for an accessory spleen prior to attempting to remove the cataract. In preparation for splenectomy the patient was twice phlebotomized and a total of 1,000 cc of blood withdrawn. He then received 1,000 cc of blood by direct transfusion from three normal donors. The Pennell apparatus¹ was employed and by this method it was possible to transfuse 500 cc of blood in eight minutes, assuring that the formed elements in the blood were a very short time outside the body. Unfortunately, technical difficulties with the platelet counting dilution fluid did not permit quantitative evaluation of the attempt to increase the blood platelets in this case. However, careful examination of blood films for platelets were made. It was felt that a very minimal increase in the numbers of blood platelets transiently occurred, but the increase was far below expectations and had disappeared completely within a few hours. The patient was operated upon the following day. There were many bleeding points but the patient did not bleed as much as was anticipated. No accessory splenic tissue could be found.

The only recourse left was to attempt to remove the cataract of the right eye in spite of the risk of hemorrhage. The alternative was blindness for the patient. Therefore a second attempt to prepare the patient was made using the same direct transfusion technique. As before, after phlebotomy, the patient received via the Pennell apparatus 1,500 cc of blood from three normal donors within a three hour period. The day prior to transfusion the platelet counts were 18,000 and 23,000 per cubic millimeter and the bleeding time was 12 minutes. The morning of transfusion the platelet count on several determinations varied between 10,000 and 16,000 per cubic millimeter and the bleeding time from 10 to 17 minutes. Immediately after the transfusion the blood platelets had risen to between 50,000 and 80,000 per cubic millimeter, the bleeding time was 3 minutes. There appeared to be a moderate increase in the numbers of platelets on the stained films. However, two hours later the platelet count had fallen to 24,000 to 28,000 per cubic millimeter and the bleeding time was 5½ minutes. An hour later the platelets were below 20,000 per cubic millimeter. The morning following transfusion (which was the morning of the operation) the platelets were 20,000 per cubic millimeter and the bleeding time was 19 minutes. During the post operative period the eyeball filled with blood, and at the time of this report, six months after operation, the patient was almost completely blind.

DISCUSSION

In each of the three transfusions reported, a minimum of 1,500 cc of whole blood was administered within a short period of time. If the blood volumes of the recipients were somewhere within the normal range, no more than three to fourfold dilution of the transfused elements would be expected. If the blood platelets were received undamaged this would mean an elevation of at least 80,000 to 100,000 in the platelet count. On the basis of the experiments with animals, a detectable platelet increase persisting for an appreciable period of time would be anticipated. However, in only one of the three experiments reported was a significant increase noted in the recipient, and even in this case it was so ephemeral as to be of little practical value.

The reasons for the unsatisfactory results are not entirely clear. In Case 1 the patient (J J) had aplastic anemia, and, presumably, the fundamental defect to which the thrombopenia was due was merely a lack of platelet precursors. Though it cannot be said with certainty, there is no reason to believe that abnormally rapid platelet destruction was a factor in this case. Yet no elevation

in platelet count occurred and hemostasis as evidenced by slow oozing of blood from the nose remained unimproved. It was thought that the use of multiple glass syringes might have meant that few or no platelets were actually being reinjected into the recipient, but platelet counts on blood allowed to stand for periods of time up to five minutes in glass syringes indicated that large numbers of these elements were undoubtedly still present in the injected blood. However, it is quite possible that qualitative alterations in platelets during their brief stay outside the body may have resulted in their premature death on reinjection. Still another possibility is that the preceding thrombopenia created an abnormal need for platelets and that the injected platelets were almost immediately utilized for this reason. This seems unlikely. It is also possible that donor platelets are not utilized in a normal manner in human subjects or that their normal rate of utilization is far greater than that found in animal experiments.

In Case 2 an attempt was made to obviate the effects on the platelets of being outside the body by using an apparatus which would reduce this period outside. The Penruell apparatus consists essentially of a short rubber tubing running between donor and recipient the blood being pulled from donor to recipient by means of a rotating worm. As much as 500 cc of blood were transferred from donor to recipient within eight minutes so that no unit of blood could have remained more than a very brief period outside the vascular system. Despite this results were disappointing and the transient slight elevation in platelet count was of no practical clinical significance. This patient (C C), of course, had idiopathic thrombopenic purpura and it is not entirely clear whether or not platelet destruction takes place at a normal rate in this disease.

It should be emphasized that the direct transfusion techniques employed are by no means comparable to the continuous endothelial anastomosis of the animal experiments. Furthermore, in the animal work there was a much longer period of mixing of the blood of thrombopenic and normal animals and larger amounts of normal blood were mixed with thrombopenic blood. If comparable conditions had been present in the human subjects the results might have been different.

A SIMPLE AND RAPID METHOD FOR DEMONSTRATING SICKLING OF THE RED BLOOD CELLS THE USE OF REDUCING AGENTS

GENEVA A DALAND, B S, AND WILLIAM B CASTLE MD
BOSTON, MASS

INTRODUCTION

THE practical importance of a rapid and simple method of detecting the sickling phenomenon is apparent to anyone familiar with the various clinical manifestations of sickle cell disease. Unrecognized, this condition may masquerade as a variety of clinical entities, including rheumatic fever, osteomyelitis, cerebrovascular accidents, and abdominal conditions such as acute cholecystitis or appendicitis, presumably requiring prompt surgical intervention. Sickleemia may also be the cause of otherwise unexplained mild or severe anemia. Thus the ready performance of a simple test for sickling of the red cells may be useful in the hospital, in the physician's office, or even under field conditions in which genetic or anthropologic studies are being undertaken.

The sickling of the abnormal red blood cells capable of this remarkable alteration of the normal discoidal form is closely correlated with the concentration of reduced hemoglobin. The sickling phenomenon appears when the oxygen tension in the gas phase with which the blood is in equilibrium is 40 to 45 mm of mercury or less.^{1,3} Below this value the oxygen tension which causes manifest sickling depends on whether the active disease or only the so called trait is present.⁴ A fall in pH within the physiologic range increases the tendency to sickling at a given oxygen tension because of the resulting greater percentage of reduced hemoglobin in the red cells. When the red cells in a sample of blood are sickled, they form an interlacing network of crescentic, filamentous structures and as a result do not separate readily from the plasma under the influence of gravity or even of the centrifuge. Consequently when a sample of blood is sickled its sedimentation rate is decreased. Due entirely to the sickling of the red cells the viscosity³ of the blood sample is also increased, as is the mechanical fragility^{5,6} of the red cells. These physical phenomena probably explain the thrombotic and hemolytic tendencies respectively which are so common in the clinical and pathologic manifestations of the disease.^{3,5}

With the possible exception of the method recently proposed by Neuda and Rosen⁹ which appears to depend on enzymic injury to the red cell surface, all clinical tests for sickling require the production of reduced hemoglobin. The resulting sickling is then judged by direct microscopic observation except when detected by the inhibitory effect of sickling on the sedimentation rate¹⁰ in the

Received for publication July 7 1948

tedious method of Winsor and Burch¹¹ Once sickled the red cells may be fixed in the sickled form with formalin solution⁴ Removal of oxygen from the red blood cells is effected either by physical means such as exposure of the blood to low barometric pressure (vacuum pump)⁴ or at normal barometric pressure by displacement of the oxygen by equilibration of the blood sample with gases such as hydrogen, nitrous oxide, carbon dioxide or nitrogen^{1,3} Oxygen and carbon monoxide cause prompt reversion to the discoidal form A second principle employed is the reduction of the oxygen tension in the blood by denying access of more oxygen to the blood while that in the sample is being consumed metabolically This may be carried out *in vivo* by causing stagnation of the circulation in a finger² for a few minutes with a tourniquet before withdrawal of a drop of capillary blood into formalin solution⁴ or for rapid coverage beneath a coverslip *In vitro* the same result may be achieved by allowing the consumption of the oxygen chiefly by the white cells of the blood sample to proceed in a sealed cover slip preparation¹² The utilization of oxygen in such a system may be accelerated by incubation at body temperature or by the addition of leucocytes⁴ or of aerobic bacteria^{4, 13} These methods are effective but do have the disadvantage of requiring special equipment such as vacuum pump gas equilibration chamber oxygen free gases stool filtrates bacterial cultures or incubator

METHOD

The simple method described here depends upon another principle namely the reduction of the hemoglobin of the red cells by a chemical agent Besides a drop of blood (which may be capillary blood taken directly from the ear or finger tip or venous blood defibrinated or oxalated) only a microscope microscopic slides and cover slips and the reducing agent are required Its only disadvantage is that because of the rapidity of its action it fails to distinguish the different susceptibilities to sickling of the red cells of active sickle cell disease and of the sickle cell trait After trying several substances ascorbic acid in the form of Ceralin was chosen It is readily available in the form of a buffered 10 per cent solution of the sodium salt with a pH of about 6.5 in sealed glass ampules containing .5 cubic centimeters Because this particular solution when diluted with water to a concentration of 2.06 per cent was found to be approximately isotonic for red cells, a small amount of a 2 per cent solution is prepared preferably from a freshly opened ampule by fivefold dilution with water immediately before use

The test has been in routine use in the Thorndike Memorial Laboratory of the Boston City Hospital for nearly two years and during this time has been taught to all Harvard second year medical students The performance of the test is as follows A small drop of the blood to be tested is placed upon a glass microscope slide and mixed with 1 or 2 drops of the diluted ascorbic acid solution The mixture is at once covered with a glass cover slip on which pressure is momentarily exerted in order to extrude excess blood and produce a blood film sufficiently thin to permit satisfactory examination of individual red cells using the high power dry objective of the microscope The preparation is inspected for the presence of sickling at fifteen minute or other convenient intervals while standing at room temperature

In originally determining the efficacy of the method the cover slips were sealed at the edges with hot paraffin for additional protection against the entrance of oxygen Control preparations were set up in a similar fashion except that either a drop of blood

Kindly supplied by Mr George B Walden of Eli Lilly & Company Indianapolis In 1940 according to Mr Walden the composition of 100 c.c. of the solution covered by a patent is used as follows ascorbic acid 11.0 Gm sodium carbonate anhydrous powder 3.5 Gm sodium metabisulfite 0.5 gram

alone or a drop of blood mixed with 1 or 2 drops of 0.85 per cent sodium chloride solution was sealed beneath the cover slip. In practice, only the preparation containing the ascorbic acid solution need be made, and the sealing of the cover slip with paraffin is unnecessary.

RESULTS

In Table I are shown the results of eighty tests for sickling made at various times on the blood of fourteen patients with sickle cell anemia, including both anemic and nonanemic individuals. In 75 per cent of the samples, definite sickling appeared within one hour when the 2 per cent ascorbic acid solution was used as described. Sickling was present in all by the end of 3.5 hours at room temperature. On the contrary, in none of fifty control samples of blood from the same patients to which either nothing had been added or, in most instances, 2 drops of 0.85 per cent sodium chloride had been added did sickling appear within an hour. Indeed, sickling was present in only about 13 per cent of the control samples at the end of three hours, and after twenty hours 11 per cent of the control samples still failed to exhibit sickling.

The figures given are summations of the number or percentage of preparations exhibiting 5 to 20 per cent sickling at the interval stated. The time for the performance of the observations on the controls at five and ten hours occurred in many instances during the night and as a result an inspection was not made. Once the preparation containing ascorbic acid had become sickled inspection of the controls tended to become less frequent. These factors led to the reduction in the number of controls observed in the interval between 15 and 20 hours as shown in the table.

DISCUSSION

That the effect of the ascorbic acid solution in causing sickling was in fact due to the reduction of the hemoglobin and not to some other action was proved by its inability to produce sickling in a hanging drop preparation, that is, one freely exposed to air. The reducing action of the ascorbic acid solution, however, for the purposes of the test described here, was shown to be independent of the rate of metabolic consumption of oxygen by the leucocytes in the preparation. Thus, high and low white blood cell counts respectively were artificially produced in different portions of a single sample of heparinized venous blood.

from a patient with sickle cell anemia. By centrifugalization of the original sample which contained 7,200 white cells per cubic millimeter, removal of the buffy coat and its addition to another portion of the sample two portions were obtained which contained respectively 4,000 and 38,300 white cells per cubic millimeter. As was to be expected from the results of others⁴ in similar experiments, sickling appeared in a sealed preparation of the blood with the high white blood cell count within forty five minutes, but failed to appear in similar preparations of the original blood and of the blood with the low white blood cell count even after fifteen hours. On the other hand, when to a drop of each of the three samples of blood was added a drop of the 2 per cent ascorbic acid solution in a sealed cover slip preparation, sickling appeared within one hour in the blood with the low white blood cell count and was observed to appear only a few minutes earlier in the other two specimens.

That besides the times saved in its performance the use of the ascorbic acid solution enhances the accuracy of the sickling test is suggested by the fact that about 10 per cent of the controls, as shown in Table I still failed to show sickling after twenty hours at room temperature. That acceleration of the process of sickling, which usually results from the incubation of the specimen may not avoid this difficulty is suggested by the recent observations of Shen, Fleming, and Castle¹⁴ who found that the red cells of patients with sickle cell disease may fail to sickle if the blood has been incubated for twenty four hours at 37.5 C in the presence of oxygen. Thus in actual practice it appears possible that if sickling in the sealed preparation in the usual clinical test is sufficiently delayed, the red cells of the specimen may lose more or less completely, the power to become sickled. Possibly an unusually slow consumption of oxygen in specimens of blood containing relatively few leucocytes may be responsible for the negative results among the control specimens. At any rate occasionally it has been our experience in the past that sickling has failed to appear in sealed cover slip preparations even when they were kept in the incubator for twenty four hours, whereas sickling was readily demonstrable in the fresh blood upon exposure to carbon dioxide gas.

Reducing agents such as methylene blue, potassium ferrioxanide thioglycolate, and lactic and succinic acids were not as efficient as the buffered 2 per cent solution of ascorbic acid for the performance of the sickling test. That other reducing substances may be employed successfully was suggested to us at the completion of these studies by the report of da Silva¹ who states that a 2 per cent aqueous solution of sodium hydrosulfite caused rapid sickling in unsealed cover slip preparations of sickle cell blood. We found this particular compound, $\text{Na}_2\text{S}_2\text{O}_4$,* not very active. Sodium thiosulfate $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ † in 2 per cent solution caused no sickling at the end of fifteen hours. Sodium bisulfite NaHSO_3 * however, in 2 per cent solution in water caused sickling of the same blood in fifteen or thirty minutes.

J. T. Baker Chemical Co. Phillipsburg N. J.
† Merck and Company, Inc. Rahway N. J.

Sodium bisulfite (metabisulfite), which is present in a concentration of 0.55 per cent as a stabilizer of the sodium ascorbate in Cevalin, undoubtedly adds to the reducing power of that solution. However, a 2 per cent solution of ascorbic acid brought to pH 6.5 with sodium carbonate and without added bisulfite produced sickling within an hour. A 0.11 per cent solution of sodium bisulfite in 0.85 per cent sodium chloride, which is the concentration of bisulfite in the five fold dilution of the Cevalin, appeared to be about as active as the diluted Cevalin itself. The 2 per cent solution of sodium bisulfite was without question the most active of the substances tested. (See Addendum.)

The probability that solutions of any reducing agent may deteriorate on standing exposed to air suggests the desirability of using solutions freshly prepared from the salt. This is easily done with sodium bisulfite, but crystalline ascorbic acid proved to be entirely too acid and consequently injurious to the red cells without the addition of alkali. Even after opening the ampule, however, Cevalin appears to keep its reducing properties in the icebox for some days although its exact rate of deterioration has not been ascertained. Although not as rapid in its action as the 2 per cent aqueous solution of sodium bisulfite, it has the practical advantage of requiring only simple dilution rather than weighing in its preparation.

Because formalin is a reducing agent it was assumed that for this reason tissues from patients with sickle cell anemia when fixed with this substance more clearly exhibit sickling of the erythrocytes than do tissues fixed with Zenker's fluid.⁵ This property of formalin is, however, not the explanation since experiments in which either previously sickled or unsickled red cells were mixed anaerobically with 10 per cent formalin in 0.85 per cent sodium chloride solution showed that the formalin fixed the red cells in whichever phase they were exposed to it. It should be pointed out, however, that the presence of sickled red cells in the capillaries of formalin-fixed tissues, though valid evidence of the sickle cell trait, does not necessarily demonstrate to what extent sickling was present during life. Sufficient anoxia to cause extensive erythrocyte sickling may have occurred only as an agonal event or only after the circulation had ceased with death or at the time of the surgical removal of the tissue. In contrast to formalin Zenker's fluid without added acetic acid when diluted to 10 per cent with 0.85 per cent solution of sodium chloride readily caused reversion of sickled red cells to more or less normal appearing discoidal forms. It is therefore probably because of this effect that the tissues of patients with sickle cell anemia when fixed with Zenker's fluid may not show the characteristically shaped red cells.

SUMMARY

A simple and rapid method of producing sickling of the red blood cells in wet cover slip preparations of the blood of patients with sickle cell anemia is described. The principle on which the test is based is the production of reduced hemoglobin in the red cells by the addition of a reducing agent. In order to perform the test, a drop of a fivefold aqueous dilution of Cevalin (approximating a 2 per cent solution of buffered ascorbic acid and also containing 0.11 per cent

sodium bisulfite) or a drop of 2 per cent sodium bisulfite Na_2SO_3 , is added to a small drop of the patient's blood on a glass microscope slide. After mixing, a cover slip is dropped on the preparation and excess blood is expressed by gentle pressure in order to produce a film of blood sufficiently thin to permit inspection of individual red cells under the high power dry objective of the microscope. With the diluted Cevalin solution, sickling of the blood usually appeared within an hour and with the 2 per cent bisulfite solution it was often present within fifteen minutes at room temperature.

Appropriate experiments demonstrated that the rate of sickling of the red blood cells caused by the ascorbic acid solution is for the practical purposes of this test, unaffected by the rate of metabolic consumption of the oxygen by the white blood cells of the specimen. It was shown that formalin although a reducing agent, promptly fixes the red blood cells in whichever form they are exposed to it, whether sickled or unsickled. Zenker's fluid however caused already sickled erythrocytes to reassume a discoidal appearance which probably accounts for the fact that histologic preparations of tissues from patients with sickle cell anemia when fixed with Zenker's fluid may not exhibit sickled red cells in the capillaries as clearly as when the tissues are fixed with formalin.

ADDENDUM

Since this article went to press two communications have been reported. Dr Janet Watson, of the Long Island College of Medicine has reported by personal communication observations made by Dr James McGovern of Bellevue Hospital New York. These investigators observed sickling in cover slip preparations occurring in less than five minutes when using a 1 per cent solution of sodium acid sulfate (bisulfite), NaHSO_4 Baker. The first appearance of any sickled cells around the periphery of the cover slip preparations was considered as the end point.

Dr Louis Thomas and Dr Chandler A. Stetson Jr have recently made a preliminary report on "Sulphydryl Compounds and the Sickling Phenomenon." These authors report sickling in less than one half hour in wet preparations made with reducing substances such as a saturated solution of hydrogen sulfide, cysteine (0.5 molar solution) and BAL (0.1 molar solution of 2,3 dimercaptopropanol).

ANTI A AND ANTI B ISOAGGLUTININ TITERS IN Rh IMMUNIZED PREGNANT WOMEN

O J BRFVDEMOEN, M D, AND C BRFVDEMOEN M D
OSLO, NORWAY

THE discovery of the ABO blood types, then heredity and antigenic properties and their significance in blood transfusions brought forth many years ago the question whether ABO incompatibility during pregnancy might be responsible for disease during pregnancy or in the newborn infant. Very few convincing cases have been reported presenting conclusive evidence that ABO incompatibility may be of pathologic importance during pregnancy.¹

On the other hand, the antigenic properties of the A and B blood groups in pregnancies with ABO incompatibility have been demonstrated several times.

Jonsson² was the first to demonstrate the presence of potent anti A and anti B lysins in the mothers about three months after the delivery as a rather selective response to A or B antigen in the fetus.

Boormau and co workers³ and Smith⁴ have confirmed this by studying isoagglutinin titers. They found only a slight increase during pregnancy, but a rapid and marked increase was seen shortly after delivery. Smith found this increase of titer only in cases where the infants were secretors.

The discovery of incompatibility in the Rh system as the most common cause of hemolytic disease in the newborn infant gave rise to new problems such as: Why is Rh immunization during pregnancy not a more common occurrence in view of the fact that the possibility of Rh immunization so often exists? And another question: Is there any relation between Rh and A or B immunization?

With regard to the latter question Levine⁵ has found a somewhat higher incidence of Rh immunization in ABO compatible pregnancies. Chown⁶ and Davidsohn⁷ found an increased AB incidence in Rh immunized women. On the other hand, Gurevitch and co workers⁸ have published two cases where there apparently might have been a positive correlation between A and Rh immunization. In conformity with this Wiener¹⁰ has found in Rh immunized women who have borne A or B children in ABO incompatible pregnancies a high anti A or anti B titer respectively.

This study, which is based upon blood samples from pregnant women, aims at an investigation of anti A and anti B isoagglutinin titers in Rh immunized women compared with adequate control material. The results thus obtained necessitated an investigation of the various anti Rh fractions. The work was carried out during the autumn of 1947.

Received for publication May 3 1948
From the State Institute of Public Health Serodagnostic Department, Chief Otto Hartmann.

MATERIAL AND METHODS

Material—The anti Rh containing sera which were examined were samples obtained from women in the last two months of pregnancy. Of 25,000 samples 87 contained Rh antibody.

Methods for Routine Rh Determination—The samples were tested for Rh in the usual manner. Cells from the coagula were suspended to 2 per cent in saline. One drop of the suspension was mixed in small test tubes with 1 drop of anti Rh serum. The tubes were incubated at 37° C for two hours, and the sediment then was examined for agglutination on slides under the microscope. Two different anti Rh testing sera were used parallelly, one containing anti D only and one containing anti D + C, both possessing good agglutinating power in saline media. Sera from all samples, including Rh positive ones, were tested by the same technique against a panel of Rh genotyped O cells. Three drops of serum plus 1 drop of a 2 per cent suspension of cells in saline were used. Sera giving dubious reactions and sera from Rh negative individuals to a great extent were examined also by Diamond's slide test or tested against cells suspended in serum and/or albumin and also partly tested by the Coombs' technique.

Storage and Control—The Rh containing sera were stored at -10° C, and groups of thirty sera then were tested. As a control for the isoagglutinins anti A and anti B, 100 sera from Rh negative pregnant women who were not immunized and 100 sera from Rh positive pregnant women were used. The control sera were picked out at random over a period of six months and were stored and handled in the same way as the sera containing Rh antibody.

Determination of the Various Anti Rh Fractions Contained in Rh Sera—The anti D fraction contained in the anti Rh sera was determined by titration both in serum and in saline media against O R₁r cells suspended in serum and in saline respectively. The serum media used were mixtures of fresh O Rh+ sera from blood donors. The titration was performed in relatively large Rh test tubes with a relatively heavy calibrated capillary pipette graduated to approximately 0.06 cubic centimeters. The same pipette was used for the distribution of dilution fluid and for the distribution of the suspension of cells. After incubation for two hours at 37° C the test was read microscopically.

The sera were also tested against O R₁r and O R₂r cells to ascertain the content of anti C and anti E agglutinins. Two drops of the serum were mixed with 1 drop of the cells suspended in saline. All of the eighty seven anti Rh sera also were tested to ascertain the content of anti C* agglutinin, all sera being parallelly tested against O R₁r and O R₂r cells in which D antigen was blocked. Blocking was performed with a serum containing anti D + E exclusively in incomplete form (blocking serum taken post partum after the third stillbirth in an Rh negative woman who was married to an R₂r or R₂R man). One volume of washed, packed O R₁r and O R₂r cells was mixed with 50 volumes of a 20 per cent blocking serum in saline, incubated for fifteen minutes at 37° C, centrifuged and washed with saline once, and then suspended to 2 per cent in saline. One drop of this suspension was added to 2 drops of anti Rh serum. Otherwise the usual technique was used.

Determination of Anti A and Anti B Isoagglutinins—The anti A and anti B isoagglutinins in all three groups were then determined in parallel series against the same Rh positive A₁ and B cells from fresh coagula. The cells were suspended to an approximately 1 per cent suspension in isotonic saline. The cells were suspended to an approximately doubled dilutions in test tubes. The titrations were performed in successively doubled dilutions in test tubes. The volumes of each serum dilution and cell suspension were 0.1 cubic centimeter. The test tube racks were then placed overnight at +5° C and afterwards for one hour at room temperature. The reading of end point titers was done microscopically against a strongly illuminated white background, direct illumination on the tube was avoided.

RESULTS

For calculating the titer results the log₂ of the conventional titer values was used (titer step values). The sera agglutinating cells in the first tube only

then have the titer value 1. In Tables I and II the arithmetic averages for the titer values in the various groups are recorded with the deviation of the means

$$\mu = \sqrt{\frac{\sum (X - \bar{X})^2}{(n-1)n}}$$

Where X is the single observation in the group

Where \bar{X} is the arithmetic average in the group

Where n is the number of observations in the group

Whether differences between the average values had any real statistical importance was tested with the formula $t = \frac{\bar{X}_1 - \bar{X}_2}{\sqrt{\mu_1 + \mu_2^2}}$

which is the difference divided by the deviation of the difference. That t is greater than 3 was taken as a sign that the difference is real (not due to chance).

Furthermore, some correlation coefficients (r) were calculated even though the material really was too small for such an analysis

$$r = \frac{\frac{1}{n} \sum X \cdot U - \bar{X} \cdot \bar{U}}{\sigma_X \sigma_U} \quad \text{where } \sigma_X = \sqrt{\frac{\sum (X - \bar{X})^2}{n-1}}$$

is the deviation of X in the group

The Antibody Content in the Sera—Prozone phenomenon against O R₀ cells in saline medium was seen in five sera, that is no agglutination in the first or in the second and third tube no prozone in serum medium. A relatively large number (four) of the sera contained anti D+C+E. For three of these sera some kind of family control was obtained. Rh negative multiparas married to men of the genotype C+, D+, E+, e+.

TABLE I. ANTI D TITERS AND THE CONTENT OF ANTI C C E IN ANTI RH SERA AND THE DISTRIBUTION TO THE ABO SYSTEM

ABO TYPE	TYPE OF Rh ANTIBODY	NUMBER	AVERAGE OF ANTI D TITERS			
			NaCl MEDIUM		SERUM MEDIUM	
A	Anti D only	23	239±	0.50	$t = 2.80$	491± 0.74
	Anti D+C	9	$t = 1.68$	$t = 3.80$	$t = 1.74$	664± 0.60
	Anti D+C+E	6				
	Anti D	4				
	Anti D+C	3	355±	0.47		
O	Anti D only	15	253±	0.62	$t = 1.66$	413± 0.73
	Anti D+C	11	$t = 1.64$	$t = 3.19$	$t = 2.60$	689± 0.76
	Anti D+C+E	6				
	Anti D	1				
	Anti D+C	1	389±	0.44		
B	Anti D only	5	340±	1.29		360± 1.16
AB	Anti D only	2	10±	0.0		260± 1.66
	Anti D+C	1				

The distribution of the anti-Rh-containing sera to the ABO and MN systems was within normal limits

The effect of the serum medium on the anti-D titer values is so marked in the complex anti-Rh sera (those containing anti-D+ C, C⁺, E) that the difference between the anti-D titer values in serum medium and saline medium is of statistical importance. The correlation between titer values for anti-D in serum medium and in saline medium is determined by the following correlation coefficients

$$\begin{aligned} \text{In A blood } r_{\text{anti-D NaCl, anti-D serum}} &= +0.34 \\ \text{In O blood } r_{\text{anti-D NaCl, anti-D serum}} &= +0.60 \end{aligned}$$

TABLE II AVERAGE TITERS FOR ISOAGGLUTININS ANTI B AND ANTI A

ABO TYPE	TITER	GROUP I	GROUP II	GROUP III
		Rh NEGATIVE WITH Rh ANTIBODIES	Rh POSITIVE WITHOUT Rh ANTIBODIES	Rh NEGATIVE WITHOUT Rh ANTIBODIES
A	Anti B	6.06	7.12	7.51
	μ	0.25	0.15	0.18
	Number	45	51	49
O	Anti B	6.41	7.40	7.73
	μ	0.29	0.15	0.19
	Number	34	40	41
	Anti A	7.79	7.60	7.81
	μ	0.30	0.16	0.16
	Number	34	40	41
B	Anti A	7.20	7.89	7.70
	μ	0.37	0.24	0.25
	Number	5	9	10

Table II shows that the anti-B titers in A and O blood in Rh negative women with Rh antibody are considerably lower than in the control group, while the anti-A titers in O and B blood show no noticeable difference between the groups. The difference in anti-B titers was tested by the method previously outlined.

ANTI B TITERS IN A BLOOD

Group III	against I	t 4.67
Group II	against I	t 3.63
Group III	against II	t 1.63

ANTI B TITERS IN O BLOOD

Group III	against I	t 4.55
Group II	against I	t 3.72
Group III	against II	t 1.38

Thus it appears that the low anti-B titers in Rh-negative women with Rh antibody compared with the control groups give differences which are too large to be caused by chance. A similar testing of the anti A titers in O blood gave values less than 1. The low anti-B titers in Rh-negative, Rh-immunized women suggests that there may be an antagonism between anti-B and anti Rh, and furthermore, a possible negative correlation between the anti B titers determined against B Rh⁺ cells and the anti-D titers determined against O R₀ r cells. The correlation coefficient for the connection between anti B titers and anti D titers in saline medium, and between anti-B titers and anti-D titers in serum medium was calculated therefore, even though the material was too small for such an analysis.

CORRELATION COEFFICIENTS (r) IN

	A BLOOD	O BLOOD
$r_{\text{anti-B anti-D in NaCl medium}}$	+ 0.43	+ 0.02
$r_{\text{anti-B anti-D in serum medium}}$	- 0.05	+ 0.11

That means that a simple negative correlation between anti B and anti D titers cannot be demonstrated

COMMENT

It is possible that the average age of Rh negative, Rh immunized women is somewhat higher than that of the control group. It is a fact that the isoagglutinin titers decrease with increasing age after adult life. Titrating the anti B in about 1,200 women of various ages. Hartmann¹¹ found a decrease of the average titer of approximately one third titer step among women between 18 and 30 years of age. The anti A titers were determined in the same way in about 700 women, and the decrease with age in titer values paralleled the decrease in anti B titer. The anti B titer in Rh negative Rh immunized women is a whole titer step lower than the anti B titers in the control group while the corresponding anti A titers show neither systematic nor definite statistical difference. A possible difference in age in the three groups does not therefore, explain why the anti B titer is so low in Rh negative Rh immunized women.

SUMMARY

Eighty seven antenatal anti Rh sera were tested to ascertain the ABO MN distribution and the content of various fractions of Rh antibody and the anti B and anti A isoagglutinin titers.

The ABO and MN distribution was within normal limits. Lower anti B titers are found in Rh negative women with Rh antibodies compared with Rh negative women without Rh antibodies and also compared with Rh positive women. The difference (one titer step) is too large to be caused by chance. A possible negative correlation between anti D and anti B titers cannot be demonstrated.

FACTORS IN THE USE OF MERCURIC BICHLORIDE FOR BIOLOGIC STUDIES

WITH ESPECIAL REFERENCE TO BLOOD COUNTS

EDNA H. TOMPKINS, M.D.
NEW HAVEN, CONN.

HAYEM¹ first used the solution which has come to be designated by his name in order to meet his need of a diluent for experimental studies with blood. He simply adapted to his needs a fixative which he was accustomed to use for tissues in general. Its widespread adoption came about during the early phases of quantitative blood studies before demands for stringent accuracy had been formulated. Various workers have found inadequacies of distribution in its use and have offered formulas for other diluents as well as suggestions to lessen this difficulty with Hayem's solution. The errors in distribution in the use of the solution usually have been attributed to clumping or balling of cells in the diluting pipettes though Joergensen² also found unequal distribution on the counting chamber filled in the manner then in vogue. The clumping usually was ascribed to the age of the diluent and to a precipitate that may occur with age. Upon development of the mechanical rotor for mixing blood, Bryan and Garney³ found that while avoidance of these factors represents important precautions, it is safer to use a diluent for red blood counts that does not contain bichloride. They suggest the use of Toison's solution. They found the distribution of cells to be very exact when the rotor was used for white counts. Clumping does not occur in white counts. Ch'u and Forkner⁴ also found that the presence of bichloride in the diluent causes clumping in certain pathologic blood, even when the pipettes are shaken by hand. They suggest that the clumping is due to the effects of the bichloride on the plasma proteins, but they did not investigate the problem from that angle and confined their studies to substitution of a different diluent, Gower's solution. These as well as other suggestions for substitution of different diluents never have received general adoption, and Hayem's solution has continued to be the diluent in common use without regard for the dangers of distribution inherent in its use. The causes underlying the inequalities of distribution in the use of bichloride for diluents were not investigated. Examination of the causes was, therefore, undertaken in an effort to so modify the formula of Hayem's solution as to avoid the dangers inherent in it, rather than to attempt further substitution of a different diluent.

It was found that satisfactory modification of Hayem's formula is possible from either of two approaches. (1) the content of bichloride can be reduced to low as that in Joergensen's solution, together with careful regulation of the pH

From the Laboratory of Applied Physiology Yale University
Received for publication May 20 1948

within a narrow zone or (2) a protective substance, such as gelatin or leechin can be added to the formula for Hayem's solution without consideration of pH up to 7.0. Use of gelatin was found to be the more practical method. The advantages of its use preparation of the solution and comparison between counts made with it and with Hayem's solution without gelatin or with Jorgensen's solution have been published briefly. The studies that follow are those that were carried out to determine the causes that underlie the clumping of blood with diluents that contain bichloride and the factors that operate in the prevention afforded by the methods found. They are presented not only because of their pertinence to the use of diluents which contain mercuric bichloride for blood counts, but also because they indicate the significance of the pH and ionic content of diagnostic and therapeutic agents in the precipitative agglutinative and colloidal phenomena of the blood.

METHODS

The studies required approach from several aspects and it seems preferable therefore on the whole, to describe the methods employed as each group of findings is presented. Consequently only those procedures will be described at this point which were used routinely to determine the data for each set of experiments.

All of the studies were made upon the blood of a single individual. Except where the studies were made on fractions of whole blood all studies were made by drawing blood into automatic pipettes, both Trenner and Hual from a freely flowing finger stick and immediately diluting with the desired solution. The pipettes were shaken a few times by hand and then rotated for thirty minutes or longer on a commercial model of the Bryan Garvey rotor. Control studies made with one of the original rotors were entirely similar. The gentleness and smoothness of the movement of the rotor together with the fact that it mixes in fixed planes, permit detection of very slight degrees of precipitation or aggregation and therefore facilitated in the elucidation of the underlying factors that feature in the occurrence and prevention of clumping in blood counts.

The occurrence of precipitation aggregation clumping and so on in the pipettes was determined by microscopic inspection of counting chambers filled as for counts. Levy Hausser chambers with improved Neubauer ruling were used.

The determinations of the hydrogen ion concentrations of the solutions were made by means of a Hellige pH meter to which were attached the glass electrode and calomel tube of a Beckmann meter. Solutions of HCl and NaOH were used for adjustments of pH. Glass weighing bottles were used as containers for the solutions and the pipettes were filled directly from them immediately after adjustment. The fluid from the pipettes was in turn expressed directly into cups when the pH of the contents was to be determined.

PRESENTATION AND DISCUSSION OF EXPERIMENTAL DATA

The experimental data are presented in Tables I to IV and in Fig. 1. The values for pH stated in the following studies and recorded in the tables represent the pH of the diluents before they were mixed in the pipettes with the blood or fractions thereof. The pH readings of the resultant mixtures were modified according to the buffering action of the different biologic fluids and curves are given in Fig. 1 to show the readings of the mixtures under various experimental conditions. The pH readings of the original diluents before experimental adjustments were as follows: Hayem's solution, 5.3; Hayem's solution plus gelatin, 4.9; Jorgensen's solution, 5.3; saline base, 6.0. All pH values

are recorded, approximately, to the nearest 0.5 reading. Blank recordings indicate lack of data at those values. Absence of reaction (that is precipitation, aggregation, or clumping) at any particular value is tabulated as zero. The presence of reaction at any pH reading is indicated by a plus sign. It does not seem important to indicate the degree or qualitative characteristics of the reaction since these are regulated, in large part, by combinations of factors such as the physical characteristics of any particular precipitation and its capacity to be rolled into balls and to catch cells, by the presence or absence of plasma or serum in any particular test of the series, by surface forces of the cells,

Fig. 1—Change in pH of diluents by admixture with whole blood or plasma

irrespective of precipitation within the plasma, and so forth. It is these factors which are often counteracted by vigorous shaking with the result that the underlying precipitation or aggregation is obscured. Therefore only the presence or absence of reaction in the pipettes at any given pH with any given diluent is tabulated, without record of the physical state of the reaction. The latter will be described and discussed where it seems significant to the understanding of the factors involved in its formation. Differentiation between certain terms used in these discussions may be aided by definition at this point. The term precipitation is employed to indicate the occurrence of diffuse, fine, crystalline particles throughout the menstruum. The terms aggregation and agglutination are employed synonymously to indicate close adherence of erythrocytes to each other without adhesive mechanism that is microscopically visible. The two states differ, apparently, only in the number of cells adherent to each other. Agglutination apparently represents aggregation of sufficient cells to cause settling of the masses. The terms clumping and balling are used synonymously to indicate the conditions usually met in whole blood when cells and precipitate unite in fibinous masses.

Action of Bichloride as a Fixative—Studies made by the addition of other unrelated tissue fixatives to the saline base of Hayem's or Jørgensen's solution indicate that the clumping effect on blood of diluents that contain bichloride (Fig 2, 3 to 6) is related to its action as a biologic fixative. The solutions to be tested were mixed with whole blood in pipettes and rotated for a short period in the manner used in making blood counts with Hayem's or Jørgensen's solution. The saline base alone caused no clumping and only questionable lysis at the hydrogen ion concentrations under study (Table I). Addition of absolute alcohol to the saline base in dilutions up to 90 per cent by volume caused lysis, above that it caused clumping similar to the clumping observed with Hayem's solution. The same statements hold for solutions of saline base and acetone. They caused lysis in dilutions up to 55 volumes per cent and clumping above that proportion. Formalin caused lysis when the pH was below 5.0. Above that, formalin caused neither lysis nor clumping in concentrations between 10 and 60 volumes per cent. Concentrations above that caused clumping. In similar manner a balance was found to exist between hemolysis

and clumping, dependent upon the proportions of bichloride added to the saline base (Table I). When added in the proportion of 25 per cent of the amount in Jorgensen's solution (0.012 Gm. to 100 c.c.) lysis alone occurred below pH 7.0, and clumping above. In a proportion of 50 per cent of that in Jorgensen's solution both lysis and clumping occurred when the pH was below 7.0, and clumping only at higher values. When the content was 75 per cent of that in Jorgensen's solution lysis accompanied by clumping occurred only below pH 6.0, while clumping alone occurred above pH 7.0. The narrow zone between these values was neutral as far as these effects were concerned—neither lysis nor clumping occurred. With full strength Jorgensen's solution, that is 0.03 Gm. per 100 c.c., the neutral zone was extended somewhat on the acid side but otherwise the events were similar to those with 50 per cent concentration. When the concentration was 125 per cent of that in Jorgensen's solution the neutral zone was extended still more to the acid side, while the events in the basic direction remained unaltered. At a concentration of 150 per cent of that in Jorgensen's solution, lysis ceased and clumping alone occurred on both sides of a neutral zone, and the reactions became more like those obtained with Hayem's solution. With the latter, lysis did not occur at the pH values tested, but clumping occurred at all pH levels, with a tendency, however, to a neutral zone in the same region as the neutral zones with the weaker solutions.

It seems obvious therefore that many, if not all, fixatives function in two ways. If sufficiently dilute they cause more or less lysis, which may or may not be accompanied by clumping of cells that have not been destroyed, the liability to lysis is influenced not only by dilution but also by the pH of the diluent. If sufficiently concentrated the fixatives no longer cause lysis but exert only a clumping action. Experimental explanation of these actions, as far as bichloride is concerned, is presented in the groups of studies that follow.

The danger of lysis as well as of clumping in the use of Jorgensen's solution as a diluent for red counts, unless the pH is carefully controlled, is obvious. The clinical significance of this is discussed elsewhere.*

The Relationship of the pH of the Diluent to Clumping in Whole Blood (Table I)—As stated previously, addition of lecithin or gelatin was found to prevent the clumping inherent in the use of Hayem's solution (Fig. 2, compare 2 and 7 with 1, 3, 4, 5, and 6). The factors involved in this protective action

Fig. 2—The low-power magnifications were obtained with a 16 mm. objective and a $\times 15$ ocular. The high-power magnifications with a 4 mm. objective and $\times 10$ ocular. The diluting pipettes were rotated for thirty minutes beginning immediately after filling. 1. Illustrates about the best distribution obtainable with standard unadjusted Hayem's solution. Even in this case the tendency toward aggregation of cells is demonstrable in the form of tiny groups scattered here and there. The pH of the Hayem's solution was 4.8. 2. Distribution with Hayem's solution containing gelatin. The mixture had been left in a Pyrex flask for many months. Aggregation of cells did not occur. The pH of the mixture was 4.0. 3. Detail of the aggregates in preparation made with Hayem's solution adjusted to pH 3.1. Small masses of cells aggregate rather tightly. Little precipitate occurs in the plasma and if present, it rarely becomes intermingled with the aggregates of cells. 4. Same solution as 1, but from a different pipette. The tendency toward aggregation of cells is more pronounced in this preparation. 5. Same as 4. Detail of the aggregates in preparations made with standard unadjusted Hayem's solution. Only a few cells occur in each aggregate and they are loosely balled with a soft amorphous precipitate. 6. Detail of the aggregates in preparations made with Hayem's solution adjusted to pH 7.2. Cells agglutinate into large tight masses and these become enmeshed with large amounts of refractive fibrinous precipitate. 7. Same as 2. Detail of preparations made with Hayem's solution containing gelatin. There is no tendency toward aggregation of cells and any precipitate remains scattered.

Fig. 9

(See opposite page for legend)

have been studied in detail for solutions containing gelatin. The gelatin was added in the proportion of 0.01 Gm. to 100 cc. of Hayem's solution. The method of preparation and the precautions have been published.⁵

It already has been shown that Hayem's solution caused clumping of the blood at all pH levels that were studied. It may be seen from Table I that when the solution contained gelatin, however, clumping was inhibited below pH 7.0. If the proportion of bichloride in the diluent was reduced to that in Jorgensen's solution (as was also discussed in the preceding section) clumping occurred on both sides of a neutral zone, between pH 5.0 and 7.0, in which neither clumping nor lysis occurred. In addition to clumping, lysis of some of the cells occurred on the acid side of that zone. As the concentrations of bichloride were reduced, lysis and clumping on the acid side of the neutral zone took place at increasingly greater pH, with consequent narrowing of the zone. As the concentrations of bichloride were increased, lysis and clumping on the acid side of the neutral zone occurred only at increasingly lower pH, with consequent widening of the zone. When the concentration was sufficient, lysis did not occur at all and the reaction became similar to that with Hayem's solution. It may be seen from Table I that gelatin afforded the same protective action against clumping with the weaker solutions of bichloride that it did with Hayem's solution. In addition it also protected against the lysis caused by weak acid solutions of bichloride. The studies with these weaker solutions reveal, therefore, something of the character of the clumping effect of bichloride better than those made with a concentration as great as that in Hayem's solution. They bring out the fact that clumping with bichloride is more intense on both sides of a middle zone of pH and that when the solution is weak enough a neutral zone at which clumping does not occur becomes definite. Addition of gelatin is effective only on the acid side of that zone.

In addition to the preceding findings with the solutions of bichloride, there also were observed qualitative, though not necessarily quantitative, differences in the character of the clumping at different levels of pH. At very low values the erythrocytes aggregated into groups that seemed free of any surrounding material (Fig. 2, 3). At higher values they also often were aggregated, but in addition they were always enmeshed or embedded in an amorphous or fibrous background (Fig. 2, 5 and 6). This background varied in appearance from a faintly amorphous character at the lower pH readings to a coarse, reactive, fibrous nature at the higher readings. The more fibrous the appearance, the more scattered were the cells in and about the background so that the clumps took on the appearance which is commonly observed when clotting has been allowed to occur before addition of the diluent.

When sodium tungstate was substituted for bichloride in the saline base and this diluent was used with whole blood in the same manner as the solutions containing bichloride, clumping occurred at all pH values when the metallic salt was concentrated, but only at pH 4.0 or below when it was weak (Table I). Similar to the reaction in solutions containing bichloride, addition of gelatin to the diluent prevented clumping in one direction of pH, but in contrast to its

effect in solutions containing bichloride it prevented clumping in the basic instead of the acid direction. In other words, strong and weak concentrations of sodium tungstate exerted an effect on whole blood analogous to that of bichloride, except that the pH level at which clumping occurred irrespective of the presence of gelatin, was reversed to the acid side. In addition, lysis was not detected under any of the experimental circumstances. These reactions between whole blood and sodium tungstate will be discussed further under Correlation and Discussion of Experimental Findings.

In summary, these studies reveal the following facts: first with concentrated solutions containing bichloride clumping of cells occurred at all pH levels but the character of the clumping varied; second with weaker solutions of bichloride a neutral zone was present at which clumping did not occur, but variable degrees of lysis, as well as clumping occurred on the acid side of that zone and clumping only on the basic side; third solutions of sodium tungstate, instead of bichloride, acted in a manner similar to solutions of bichloride except for reversal of the critical level of pH; clumping occurred at all levels with concentrated solutions, but on the acid side only with weak solutions; fourth, gelatin gave protection from the clumping of blood with solutions of mercuric bichloride below pH 7.0 or sodium tungstate above pH 6.0. It also protected the cells from lysis with weak acid solutions of bichloride.

It is obvious that clumping of the blood is associated with the presence of metallic salts and is prevented by the addition of gelatin at certain ranges of pH, the range varying with the salt employed. The following studies were carried out to determine the part played by the different fractions of the blood in the clumping and the nature of the forces that respond to pH and of those that are inhibited by gelatin.

Studies With Whole Washed Erythrocytes (Table II).—Blood for these studies was collected by venous puncture in tubes containing either dried sodium citrate or 1 drop of a concentrated solution of sodium oxalate. The tubes were centrifuged and the plasma was collected separately for studies to be described later. The cells were washed with about 10 volumes of physiologic saline centrifuged, separated, and rewashed until the process had been repeated six or more times. The erythrocytes were then suspended in equal volumes of saline and the suspension was used with the pipettes and various diluents in the manner and under the conditions described in the studies with whole blood. These plasma free cells were found to aggregate, or agglutinate not only with Hayem's solution but also with all dilutions of Jorgensen's solution employed almost irrespective of the pH. The aggregation was similar to that observed with whole blood in Hayem's solution at very low pH values (Fig 2, 3). That is the aggregates appeared free of any amorphous or fibrous background. The aggregation was inhibited by gelatin below pH 6.5. With sodium tungstate, on the other hand, aggregation of erythrocytes occurred only on the acid side and was unaffected by gelatin.

It is obvious from these findings that while the fibrous qualities in the clumping of whole blood with bichloride are related to the presence of plasma, aggregation of the erythrocytes is independent of the plasma. Furthermore,

it is obvious that plasma actually gives protection from aggregation in the neutral zone when the metallic salt is weak enough. Gelatin acts as a more potent protective agent and protects even with strong solutions of the metallic salt.

Lysis did not occur with the weak solutions of bichloride as it did with whole blood. It seems probable that the more fragile cells had been lysed automatically in the process of washing and that the remaining cells were sufficiently resistant for the conditions of the experiment.

Studies With Lysed, Washed, Erythrocytes (Table II)—The saline suspensions of erythrocytes that were used for the preceding studies with whole washed erythrocytes were centrifuged and freed of as much saline as possible. They were lysed by the addition of about twice their volume of distilled water. The solutions were centrifuged and the supernatant fluid was filtered through

No 5 Whatman paper No membranes could be found by microscopic examination after this treatment. The filtrate was subjected to tests similar to those employed with whole erythrocytes. If sufficient of the filtrate was used, it was precipitated by either Hayem's or Jorgensen's solution at all hydrogen ion concentrations studied, and the precipitation was not prevented by the presence of gelatin in the diluent in the usual proportions. With sodium tungstate, precipitation occurred up to but not beyond pH 4.5. There was no difference between the reactions of the erythrocytes that had been procured by the use of oxalate and those procured by the use of citrate.

The unprotected, washed erythrocytes obviously had reacted to the diluents in accord with the reactions of their contents to the same diluents but they could be prevented from certain of the reactions by the presence of gelatin while the contents were not thus protected from reaction. It would seem therefore, that gelatin must function by protecting the surface of the erythrocytes from contact with the metallic salt but not beyond certain critical pH values. These values vary according to the nature of the metallic salt.

Studies With Plasma and Serum—The plasma and serum for these studies were obtained at the same time as the cells used in the preceding studies. The plasma used was from the oxalated specimen only. These fluids were subjected to tests similar to those made on blood and cells. As in the case of the contents of lysed erythrocytes if sufficient plasma was used it was precipitated at all hydrogen ion concentrations tested by either Hayem's or Jorgensen's solution and this action was not prevented by the presence of gelatin in the usual proportion. In order to simulate the conditions that exist in making blood

† See footnote † Table I

counts, therefore, studies were also carried out on plasma drawn only to the automatic stop of the pipette (Table III). Under those circumstances it was not precipitated below pH 5.0 by the solutions of bichloride or above pH 6.0 by those of sodium tungstate. As was the case when larger amounts of plasma were employed, these precipitations with lesser amounts also were not prevented by the presence of gelatin in the usual proportions.

The findings with serum varied from those with plasma in two respects: the serum was not precipitated as easily nor at as low a pH with the weak solutions of bichloride as was the plasma, and it was not precipitated at all by the amounts of sodium tungstate that caused precipitation of the plasma.

CORRELATION AND DISCUSSION OF EXPERIMENTAL FINDINGS

With amounts equivalent to those present in blood counts, plasma was not precipitated by Hayem's solution below the isoelectric point of any of the usual plasma proteins. Precipitation did occur above that point, but the precipitation was at first soft and slight and fluffy, and it was only as the pH rose to levels above the isoelectric point of most of the common plasma proteins that precipitation became sturdy and abundant enough to ball with rotation. The same statements may be made of the reactions to Jørgensen's solution. Gelatin did not affect these precipitations. Yet gelatin prevented clumping in whole blood at hydrogen-ion concentrations equal to those at which precipitation of plasma proteins occurred. Obviously the clumping in whole blood is due to factors other than just the action of the metallic salts on the plasma proteins alone.

The washed erythrocytes aggregated, or agglutinated, at all pH levels with any dilution of the mercurial, and this could be prevented with gelatin up to pH 6.5. Yet if weak solutions of the mercurial were used with whole blood, clumping did not occur in a neutral zone. Therefore the plasma proteins gave protection from aggregation despite the fact that they themselves were not prevented from precipitation at this hydrogen-ion concentration. Again, obviously, the plasma proteins are not the entire cause of clumping in whole blood, and they are even somewhat protective, though less so than gelatin.

Irrespective of the presence of the plasma proteins then, clumping occurs in whole blood at all pH levels with concentrated bichloride solutions, and on either side of a neutral zone with dilute solutions. The clumping with both the weak and strong solutions of bichloride is prevented up to a certain critical pH of 7.0 by the addition of gelatin. Since the washed erythrocytes aggregated, or agglutinated, at all hydrogen-ion concentrations, even with the dilute solutions of bichloride, and the aggregations could be prevented up to pH 6.5 by the addition of gelatin, it seems obvious that the factors which cause aggregation of erythrocytes in the presence of the metallic salt also regulate the clumping in whole blood with this salt.

The contents of the lysed erythrocytes precipitated at all pH levels and this was not prevented by gelatin. The contents were obviously subject to reactions similar to those which characterize plasma proteins. Without gelatin the washed erythrocytes responded much as their contents. Yet gelatin protected them from aggregation up to pH 6.5. It is obvious that intact erythrocyte

exert a somewhat different or more concentrated force than that of free proteins, and it is this which can be prevented up to a certain point by the protective agent, gelatin. They apparently function, when whole as large electro-negative colloids which aggregate in the presence of positive ions.

Granted that they do function as electronegative colloids the aggregation of erythrocytes in whole blood with weak solutions of bichloride on the far acid side of a neutral zone in which aggregation did not occur can be explained on the basis of colloidal aggregation due to the presence of sufficient positive electrolytes.

The occurrence of agglutination on the basic side of the neutral zone in contrast to that on the acid side, may be due to the fact that the gelatin itself is precipitated at this pH (Table IV). On the other hand it may be due to direct reaction between the bichloride and the contents of the erythrocytes at a pH concentration above the isoelectric point of hemoglobin. Gelatin did not prevent precipitation of plasma proteins at pH concentrations above their isoelectric points, even when those concentrations were less than the pH at which gelatin could be inactivated by precipitation. It seems probable therefore, that the aggregation of erythrocytes at pH 7.0 in whole blood or 6.5 with washed cells, was due to the inherent character of the cellular contents rather than to the precipitation of the gelatin. The studies with sodium tungstate and washed erythrocytes seem to support these conclusions. Colloidal aggregation above a pH at which direct union could occur between the metallic radical and the proteins within the cells was apparently suppressed by the presence of negative electrolytes. The explanation of the capacity of concentrated solutions of sodium tungstate to cause clumping in whole blood at high pH concentrations and of the protection afforded by gelatin, in contrast to this reaction with washed erythrocytes is not clear.

Whenever aggregation of erythrocytes occurs at pH levels at which precipitation of the plasma proteins may also take place the aggregation is accompanied by a background of more or less amorphous or fibrous material. It would seem that while the precipitated plasma proteins are not in themselves sufficient to initiate clumping they do qualify and intensify it if aggregation

*See footnote † Table I

or agglutination of the erythrocytes occurs. It is by this inhibition from aggregation that more vigorous shaking or the presence of gelatin acts to prevent clumping until critical pH levels occur.

That the clumping with weak, dilute solutions of bichloride at pH levels below those at which the plasma proteins precipitate was, nonetheless, accompanied by a fibrinous background is probably due to the lysis that occurred at those levels with liberation of cellular contents which could precipitate at such low levels. The precipitate then would have balled with the aggregated erythrocytes in the same manner as do precipitated plasma proteins when they occur in the presence of agglutination.

In summary then, these studies seem to indicate that erythrocytes are aggregated by electrolytes as electronegative colloids at pH concentrations below the isoelectric point of hemoglobin and by direct union with metallic salts under the same conditions that function for proteins in general. Gelatin prevents the colloidal aggregation, or agglutination, but not that due to direct chemical union with its accompanying precipitation and coagulation of the erythrocytic contents. The plasma proteins are precipitated at their specific isoelectric points. This precipitation alone is insufficient to cause clumping in the pipettes. If the cells aggregate, on the other hand, because of their own forces and irrespective of the events occurring in the proteins in which they are suspended, then the precipitated proteins serve to qualify and further facilitate clumping by becoming balled with the cells and in turn entangling more cells. Balling and clumping are exaggerated and emphasized with the gentle and regular motion of the rotor, but are inherent in the reactions of blood with bichloride. When the cells are protected from aggregation the rotor is unable to produce clumping. As Ch'u and Forkner⁴ found with hand shaking, these same features are naturally present in other methods of shaking. It is merely that most methods of shaking offer enough violence and shift of direction that the colloidal aggregates are prevented from holding, and in that case the precipitated proteins do not find a nucleus for collection and a reciprocal entangling of more cells. Clumping therefore is not in evidence with such methods of shaking, but the underlying potentialities are present nonetheless, and the dangers of clumping are always present. Ch'u and Forkner⁴ found this to be particularly true in certain pathologic conditions.

The experimental findings are significant from the standpoint of various clinical and biologic studies other than blood counts, and a brief survey of certain of these seems indicated.

The fact that modifications in pH in the presence of tissue fixatives can effect such marked changes in erythrocytes as lysis or agglutination, respectively, emphasizes anew the importance which Petrunkevitch⁶ ascribes to pH in the fixation and staining of tissues. The misconceptions that may occur because of failure to evaluate this factor are discussed in many texts on histologic technique. The fact that differential precipitation of the different elements of the blood exposed to the same fixative may occur simply under the influence of different hydrogen-ion concentrations indicates possibilities for differential analysis of the finer cytology of tissues. Obviously the differences in the way

tissues react to the same stain are due not only to the simple acid base relationships upon the stains or between the stains and the tissues but also are determined by the physical state of each element in the tissues that, in turn, having been determined by the pH of the fixative in relation to the elements in question. These possibilities are very beautifully illustrated in the differential staining of anatomic cross sections which Fohm⁸ has obtained with aniline blue used at different hydrogen ion concentrations.

The lysis of erythrocytes that has been shown to occur in weak solutions of bichloride and of the other fixatives employed is probably due either to solution of cell membranes or to some sort of union of the membranes with the fixatives involved in such a manner as to weaken the membranes and allow extrusion of the contents before coagulation or fixation of the latter can occur. In the case of the weak solutions of bichloride the union is probably with the lecithin of the capsule while the concentration of bichloride or the pH or both are insufficient to permit coagulation of the proteins. In stronger concentration the amount of bichloride is sufficient to coagulate or fix the proteins of the cells even as it unites with the lecithin of the capsule. The action of gelatin as a protective colloid applied to the surface of the erythrocytes probably explains its effect in preventing lysis just as it prevents agglutination.

The capacities of dilute solutions of fixative agents to cause lysis and especially of very dilute solutions containing mercury at hydrogen ion concentrations equal to those which obtain in blood and tissues place significance upon the possibility of equivalent action in local or generalized areas subjected to therapeutic agents of similar nature.

It is significant that the hydrogen ion concentration of the blood is such as to favor precipitation of plasma proteins and agglutination of erythrocytes in the presence of electropositive metals and colloids especially those represented by a heavy metal like mercury. The importance of this fact in therapeutic and diagnostic procedures employing such solutions is obvious. When such solutions are used for parenteral therapy for instance the events when they meet body fluids must often mark the difference between smooth and stormy reactions. And in such diagnostic procedures as the use of Hayem's solution^{9, 10} or other solutions containing bichloride^{11, 12} in studies of liver function, the ambiguities might well be lessened by regulation of the pH. The recent work of Kunkel¹³ with solutions of copper or zinc for a similar purpose certainly shows the importance of pH in the results and interpretations of such tests.

The dangers of unpredicted agglutinations are lessened in the presence of the correct protective colloids for the situation at hand but the protection from such colloids may be negated by elevation or depression of the pH of the environment to that at which the colloid itself is precipitated by the reagent.

The fact that the gentle rotation of blood in the fixed planes set by the Bryan Garrey rotor brings out the inherent tendency for precipitation and clumping in red blood counts suggests that similar motion might prove useful in biologic and diagnostic procedures that require detection of the phenomena of precipitation or agglutination. In certain respects the method achieves the

same results as are sought at times by vibratory mechanisms.¹⁴ In the present studies the method actually allowed detection of the phenomenon of aggregation when it was masked by the more violent vibration of a shaker or even by hand shaking.

The risks inherent in the use of soft glass containers are once again illustrated in the present studies. Storage of Hayem's or Joergensen's solution in soft glass containers quickly resulted in massive clumping with whole blood under conditions in which this phenomenon did not occur if the diluents were stored in Pyrex containers. These effects were caused not only by changes in pH due to reaction with soft glass, but also by changes in the content of electrolytes.⁵ Since the findings and the interpretation of them are obviously tremendously influenced by the pH and the electrolytes of the test solutions in diagnostic procedures based on precipitative or agglutinative phenomena by means of solutions containing heavy metals, the dangers of change in these factors by improper storage are very real. The reactions between the metal and the biologic substance in question may be encouraged, suppressed, or confused by reactions of other substances, depending upon these factors.

The power of erythrocytes to attract and carry colloidal substances, while recognized, is given far too little consideration in biologic studies. The action of gelatin, and to a lesser extent, that of the plasma proteins in the prevention of aggregation of erythrocytes in these studies illustrates the surface force of the erythrocytes, even as it indicates the colloidal activity of these proteins. The studies of Bloom^{16, 17} indicate that after fats have been absorbed from the gut they first are attracted from the plasma to the cells of the blood before chemical changes can take place within the cells. Pennell¹⁸ recognizes surface attraction between erythrocytes and platelets in his concept of a causal relationship between erythrocytes and hemophilia.

CONCLUSIONS

The factors involved in the clumping of blood in red counts made by the aid of mechanical rotation are inherent in the interactions of Hayem's solution with plasma and cells and are merely emphasized by rotation. The capacity of rotors to demonstrate the phenomena of precipitation and aggregation and/or agglutination in blood counts was found useful in elucidation of the factors involved in these phenomena.

The clumping is due to the reactions of mercuric bichloride with the cells and the plasma as a tissue fixative. These reactions are regulated by (1) the concentrations of bichloride, (2) the relationship of the pH of the diluent to the isoelectric points of the erythrocytic contents and of the plasma proteins, and (3) the colloidal activities of intact erythrocytes.

When dilute enough, bichloride may cause lysis. When concentrated enough it causes colloidal aggregation and/or agglutination of the erythrocytes and precipitation of proteins, depending upon the pH. Addition of gelatin to the diluent protects the cells from lysis and aggregation at hydrogen ion concentrations below pH 7.0, but does not affect the precipitation of proteins.

Aggregation of the erythrocytes and precipitation of the proteins under the action of bichloride occur independently of each other. Aggregation alone may simulate clumping. Precipitation of the plasma proteins alone does not cause clumping. When aggregation accompanies precipitation characteristic clumping occurs.

The findings are discussed from the standpoint of their significance in relation to problems other than blood counts. They bear upon the phenomena of lysis, precipitation, and agglutination upon diagnostic and therapeutic measures which involve colloidal or precipitative reactions and upon the differential responses of tissues to fixation and staining.

MEASUREMENT OF THE ELECTRIC RESISTANCE OF HUMAN BLOOD, USE IN COAGULATION STUDIES AND CELL VOLUME DETERMINATIONS

ROBERT L. ROSENTHAL, M.D., AND CHARLES W. TOBIAS, PH.D.
BERKELEY, CALIF.

THE measurement of electric resistance and conductivity is a universally recognized physical-chemical procedure which has had wide use in biologic investigations. It has been successfully used in the study of cell permeability, muscle physiology, and so forth, and attempts have been made to measure electric resistance changes during the blood coagulation process. Most of the results obtained have indicated that there is no blood resistance change during coagulation. A review of the literature reveals that most of the work done on this subject was published before 1926 and centers around resistance or conductivity as related to cell volume and coagulation. Stewart and others¹⁻⁵ have shown that the resistance of blood is directly proportional to the cell volume. Blood may be thought of as a suspension of cells, which are very poor conductors, and plasma, whose conductivity depends upon the concentration of electrolytes, particularly sodium chloride⁶. Sigman and co-workers⁷ measured the resistance of beef blood flowing through a tube. They reported that the resistance decreases with increasing flow velocity. Other workers⁸⁻¹⁰ have employed resistance measurements in studies of hemolytic and osmotic behavior of the red cell. Resistance of packed red cells, normally thirty to forty times the resistance of plasma, is reduced to a value comparable to that of plasma by saponin hemolysis.

Most authors were unable to demonstrate reproducible electric resistance changes during the complex process of blood clotting¹¹⁻¹⁴. In the only recent report, Giaff and co-workers¹⁵ say that there are irregular resistance changes during clotting, not related to clotting time, and that the resistance of heparinized blood measured in vitro steadily increases in the first half hour after obtaining the blood sample.

In the present paper a reliable and practical experimental method is described for the measurement of electric resistance of blood and other fluids. Observations are presented to show that this method enables one to make reproducible resistance versus time measurements on whole blood and that the varying observations of previous investigators may have been due to inadequate technique. These observations apply to changes in blood resistance during coagulation and to the relation between blood resistance and cell volume fraction.

METHOD

The application of the classic method of Kohlrausch and Holborn¹⁶ and its elaboration worked out by Washburn and others has been widely accepted for the measurement of the electric resistance of colloid systems and suspensions. Taylor and Acree,¹ Washburn and Weiland,^{18, 19} and others^{20, 2} have given excellent discussions of the theoretic principles. It is beyond the scope of this paper to discuss technical details other than those applying especially to the determination of the resistance of blood. Most of the experimental arrangements for blood resistance measurements reported in the literature appear to have been unduly complicated and time consuming and intended for a limited number of measurements. We believe we have designed a setup which can be used to study the clotting of blood, permitting rapid successive resistance measurements. The method has high reliability of single measurements and it could be adapted to measurement of other biologic materials.

Fig 1 shows the measuring tube and electrodes. The tube made of Pyrex, was 12 mm in diameter and could be held in any test tube rack. The electrodes, consisting of lightly platinized* platinum plates 0.01 inch in thickness $\frac{1}{4}$ sq cm in area, and $\frac{1}{2}$ cm apart, were designed to be large enough to avoid the errors arising in the use of wire point and small electrodes and yet to require only about 15 cc of blood or other fluid. Platinized electrodes eliminated the necessity of extrapolating the measurements to infinite frequency as required in the case of unplatinized (bright) electrodes, and they gave a sharper end point of impedance balance. Also measurements during clotting made with unplatinized electrodes often showed discrepancies which could be explained by imperfect adherence of the clot to the electrodes. The electrodes were cleaned satisfactorily by connecting them as cathode in 20 per cent sodium hydroxide and applying 3 volts for two minutes. The adherent fibrous material loosened by this process readily washed off with hot distilled water.

The position of the electrodes in relation to the measuring tube and blood clot determines the result of measurement to some extent. In the geometry used in the present experiments the electrodes were entirely contained within the clot and they remained in the clot during retraction (see Fig 2). This enabled us to study the change of resistance during clot retraction for a considerable length of time. Unfortunately, some previous investigators did not describe their electrode arrangements. It was found by us that if electrodes are placed too distantly or in an inconvenient way the clot may break off during the process allowing plasma to interfere with the clot resistance measurement. The results obtained with such latter electrode arrangements are irreproducible.

An audio frequency oscillator capable of producing an alternating current frequency from 20 to 200,000 cycles per second was used to generate power. Since measurements with the platinized electrodes showed negligible variation with frequency 1,000 cycles A. C. was used through the experiments.

The impedance bridge† provided an accuracy adequate for our purposes with a probable error of less than 1 per cent and a maximum error of 2 per cent. The amplitude of the applied voltage was 0.25 volts root mean square. Capacitance of the measuring cell circuit was negligible and compensation did not alter the readings. Our parallel control observations showed that the behavior of clotting blood was not changed beyond the range of experimental error by the current used in the measurements.

Instead of using the conventional telephone bridge balance indicator, an oscilloscope‡ was used. The horizontal sweep was connected to a 60 cycle saw tooth power supply. The

*Electrodes were platinized with Lummer 1 urbaum solution 0.3 Gm. platinum chloride 0.002 Gm. lead acetate dissolved in 10 cc. of distilled water. Six volts were applied, each electrode connected as a cathode for thirty seconds. Electrodes were cleaned by N. sulfuric acid, connected as anode 3 volts for 1 and one half to minutes. Electrodes had to be replatinized when the platinum black surface became inefficient.

vertical sweep showed the amplified 1,000 cycle A C voltage appearing between the unbalanced junctions of the impedance bridge. At balance, the vertical amplitude reached a well defined minimum.

By means of a selector switch and parallel circuits, six different samples could be studied at one time. All determinations were made in a constant temperature water bath set at 37° C (See Fig 3). An increase in temperature of 1° C produced an approximate 2.3 per cent decrease in resistance. The conductivity cell constant was measured with 0.1 KCl and all measurements were converted to specific resistance in ohm centimeter units by the relation

$$\text{Specific resistance at } 37^{\circ} \text{ C} = \frac{\text{Measured resistance of blood}}{0.0158 \times \text{Measured resistance of } 0.1 \text{ N KCl}}$$

where the factor 0.0158 is the specific conductance of 0.1 N KCl at 37° C

OBSERVATIONS

Resistance Changes During Blood Coagulation—15 cc of blood drawn with a dry syringe were carefully placed in the measuring tube, the electrodes were inserted, and measurements were made at frequent intervals for forty minutes. Parallel clotting time determinations were performed by a modified Lee-White method (½ cc of blood, two tubes 10 mm in diameter). The results are shown in the two curves in Fig 4, with time plotted against specific resistance in ohm-centimeter units. The lower curve represents the

average of measurements on sixteen blood normal specimens while the upper one is composed of the average of fourteen polycythemic blood samples. All blood samples showed clot retraction. The curves for two individuals together with the clotting times are shown in Fig 5. For the first few minutes the resistance value was constant at a level indicative of the cell volume per cent. Then at the time clotting occurred, the resistance started to increase. This increase, which is related to clot retraction has been found to continue for at least seven or eight hours. Each of the determinations followed this pattern, with variations occurring in the magnitude of resistance point of beginning resistance increase, and slope of the curve. The higher value for the one minute determination could be explained by the temperature adjustment and possibly by insufficient time for thorough wetting of the electrodes. The slight drop in temperature of the blood while in the syringe would increase the resistance 2.5 per cent for each degree centigrade.

Definite substantiation of clotting as the factor responsible for the time resistance curve pattern described was obtained by observations on blood rendered incoagulable by the *in vitro* addition of heparin (0.1 mg.) or oxalate (18 mg. ammonium and 12 mg. potassium oxalate). The unclotted blood gave no significant change in resistance over a one hour period as seen in Fig 6 which also shows the same blood, without any addition of an anticoagulant giving the typical clotting pattern. Very slight variations in resistance were the probable effect of red cell sedimentation to produce changing cell

concentrations around the electrodes. It was found that shaking or stirring the unclotted blood increased the resistance, which dropped in one or two minutes to a constant value about 6 per cent lower as the cells settled.

*Resistance and the Cell Volume Fraction of Blood**—The electric resistance of plasma is much lower than that of blood cells alone. Whole blood resistance is determined by the intrinsic resistance of plasma and cells and by the relative amount of cells and plasma present in the blood. It also has been shown that the shape of the red blood cells influences whole blood resistance. Ponder⁴ has presented a formula for calculating the cell volume fraction of a sample of blood from the measurement of the resistance of both the unclotted blood and its plasma separated by centrifugation.

$$\text{Cell volume fraction} = \frac{\phi - 1}{\phi + \frac{1}{X}}$$

Where $\phi = \frac{\text{resistance of blood}}{\text{resistance of plasma}}$ and X is the form factor dependent on the

shape of the cells, assumed to equal 1.10 for red cells in plasma. Also, cell volume per cent = cell volume fraction $\times 100$.

In the present study the cell volume per cent was determined by both electrical resistance measurements and centrifugation (Wintrobe tube heparinized blood, 2,500 revolutions per minute for one half hour reading represent red cell volume) on aliquot samples of venous blood. Plasma values averaged 63.2 ohm centimeters with a range of 61.0 to 66.8 ohm centimeters. The blood resistance, taken as the average value of the three four and five minute readings of the time resistance curve ranged from 131.2 to 230.9 ohm centimeters. A comparison of the results obtained by the two methods revealed that the resistance determinations were 7.7 per cent lower than the centrifuge values in normal subjects and 7.8 per cent lower in patients with polycythemia vera for average values (see Table I). In three leucemic blood specimens with an average white count of 96,200 the resistance method compared 5.7 per cent higher than the centrifuge method. This may be explained by the fact that while only the red cell volume was recorded for the centrifuge cell volume, the resistance measurement accounted for the high, poorly conducting white cell volume as well as the red cell volume. For normal or only slightly elevated white counts the white cell resistance factor was very small.

The cell volume per cent can readily be determined from resistance measurements by taking the ratio of blood to plasma resistance (ϕ) and re-

Since the precise meanings of the terms cell volume and hematocrit are at the present time confused, we deem it advisable to clarify certain terms used in this paper. Hematocrit is used in its strict sense to refer to the volume of packed red cells expressed as a per cent, obtained by centrifugation of 1 c.c. of blood in a tube 100 mm. long. The term cell volume has been used to designate the proportion of cells by volume in a given sample of blood; the total cell volume of an animal or volume of an individual cell. In this paper the term cell volume fraction is used to indicate the proportion of cells by volume in venous blood irrespective of the method used in its determination. The volume per cent of cells in the blood sample is termed cell volume per cent irrespective of its method of determination. Since the volume of white cells unless abnormally increased as in leucemia, is very small the cell volume per cent approximates the red cell volume.

fering to a curve of the cell volume per cent values calculated from Ponder's equation plotted against ϕ as in Fig 7. The values obtained by the centrifuge method are plotted against ϕ for comparison. Table II lists some pertinent data on subjects used in these measurements.

Fig 7—Ratio of blood to plasma resistance (ϕ) plotted against cell volume per cent, white count and red count for seventeen subjects. The absence of a simple relation between blood resistance and white and red counts is shown. There is a direct relation of resistance to cell volume (chiefly red cell). The curve represents cell volume per cent values obtained by calculation from Ponder's formula using the ratio of blood resistance to plasma resistance (ϕ).

In order to obtain a wider range, heparinized blood was diluted and concentrated by varying the proportion of cells to plasma, and cell volumes were determined by the two methods on aliquot samples. The blood resistance measurements were obtained immediately after shaking, before settling had occurred. Results, shown in Table III, indicated that the resistance determinations were 61 per cent lower for the normal group, 81 per cent lower for polycythemic groups, and 20 per cent lower for the leucemic group. The combined normal and polycythemic groups gave a value of 73 per cent.

The level of blood resistance showed no direct relation to hemoglobin, red cell count, white cell count, or platelet count. Fig 7 shows the red and white counts plotted against the blood-plasma resistance ratio (ϕ).

DISCUSSION

Our results show blood resistance measurement to be of value in the study of blood coagulation, both as a method for the detection of the clotting time and as a means for obtaining the quantitative measurement of the rate of clot retraction. The advantage in the use of electric resistance lies in the fact that a dynamic process such as blood coagulation may be studied under controlled conditions without disturbing the process by the making of measurements.

Emphasis must be placed upon the importance of the geometric orientation of the electrodes to the clotting blood and retracting clot in the evaluation of observations and data. We located our electrodes at the central part of the blood and within the retracting clot. As soon as the blood has clotted, clot retraction begins by the contraction of the fibrin network which pulls the large elements or cells together into a dense mass, thus displacing the serum to the periphery. This process produces increases in resistance measurements because it simultaneously increases the concentration of poorly conducting cells and decreases the concentration of serum, a good conductor, between and around the electrodes. On this basis it is possible to relate our observed changes in resistance during clotting, as graphically demonstrated by the time resistance curve, to blood coagulation events. Prior to clot formation there is no significant change in resistance. The clotting time and start of clot retraction are marked by the first increase in resistance. Thus the clotting time may be determined with the elimination of motion, the source of considerable variation and inconsistency in most methods in common use.

The subsequent increases in resistance result from retraction of the clot. Therefore the slope of the rising portion of the time-resistance curve may be assumed to correspond to the rate of clot retraction and to serve as a quantitative measure of this process. Since there has been no method previously available for a comparable quantitative study of clot retraction, such measurements may serve to detect significant differences in and variations of this process in disease. The method also may provide a means to determine the effect of chemical and therapeutic agents upon clot retraction.

Our results differ from those reported by Giaff and co-workers¹⁵ who obtained an increase in resistance of normal blood during the first ten minutes unrelated to clotting time, while heparinized blood gave a rapid progressive increase in resistance for twenty to thirty minutes. The description of the method given by these authors is not complete enough to allow us to compare their data with ours. Certain important features of their method such as the use of 60 cycles A.C. and applied voltage of 5 volts root mean square appear to be at variance with accepted procedures which have been thoroughly worked out for conductivity measurements.

It is of investigative interest to compare the cell volume fraction calculated from resistance measurements with the centrifuge hematocrit. It has been known for some time³ that hematocrit values obtained by separation of cells from plasma in the centrifuge do not give the true cell volume fraction. This

would be true only if the centrifuge would pack the cells so closely that all intercellular space and plasma would be excluded from among the cells. For example, Miller²⁶ and Kennedy and Millikan² demonstrated that in order to achieve such perfect separation, centrifugal force of a magnitude that would destroy the cells themselves would be required. There are a number of papers available which compare various methods for the determination of the cell volume fraction with the centrifuge method. Kennedy and Millikan² and Shohl and Hunter²⁸ reported values obtained by using dye dilution of plasma 10 to 12 and 4.5 per cent, respectively, below the centrifuge hematocrit. Chapin and Ross²⁹ found the cell volume fraction determined by dye dilution (T 1824), protein dilution, and the use of red cells tagged with radioactive iron to be an average of 8.5 per cent lower than the cell volume fraction obtained by centrifugation. Ponder and Saslow¹ calculated the cell volume fraction in whole blood from direct measurement of the dimensions of the individual red cell and then number. This calculated value was in close agreement with the dye dilution determination of the cell volume fraction of the same blood. Stewart³ used the method of conductivity and also obtained values below the centrifuge hematocrit (5 to 6 per cent). The results presented in this paper indicate that the cell volume fraction determined by electric resistance measurements is 7.7 per cent lower than values obtained by centrifugation. Thus the dye dilution, protein dilution, tagged red cell, direct measurement, and electric resistance methods agree very well in the determination of the fractional volume of red cells in blood, while the value obtained in the centrifuge hematocrit is consistently high because of plasma trapped between the packed red cells.

SUMMARY

A reliable rapid method for the measurement of electric resistance of small amounts of blood or similar material is presented.

A pattern of change in the resistance of blood during coagulation is described. These resistance changes make possible the determination of the clotting time with elimination of inconsistencies caused by motion and offer a quantitative means for the study of clot retraction. In view of the fact that no method has been available previously for a comparable quantitative study of clot retraction, electric resistance measurements may serve to detect significant variations of this process in disease beyond our present knowledge.

By means of the ratio of blood resistance to plasma resistance the cell volume fraction of a sample of blood may be calculated. Cell volumes determined by resistance measurements were found to average 7.7 per cent lower than the hematocrit as determined by centrifugation.

The authors wish to thank Dr. J. H. Lawrence and Dr. C. A. Tabias for their continued interest and assistance and to acknowledge the help of Mr. Leo Lipetz, Fellow in Medical Physics of the Dazrin Foundation.

THE EFFECT OF CHOLINE, METHIONINE, AND LOW FAT DIET ON THE LIFE EXPECTANCY OF PATIENTS WITH CIRRHOSIS OF THE LIVER

LEO WADE, M D , LOUIS NEUDORFF M D HERBERT FRITZ M D , AND
MICHAEL KARL M D
St Louis Mo

IN A previous communication from this clinic a regimen for the treatment of cirrhosis of the liver was described.⁶ This regimen was based upon two assumptions first, that fatty changes in the liver ordinarily precede the more characteristic anatomic lesions of cirrhosis second that fatty changes in the liver may be dietary in origin especially in the alcoholic patient and hence might be comparable to the changes observed in experimental animals placed on deficient diets. The clinical course of several patients was described. The results attributed to the therapy were striking in each instance. It was pointed out, however, that not all patients had responded so dramatically and that spontaneous remissions have long been known to occur in the absence of any specific therapy. Interpretation of the efficacy of the therapeutic regimen therefore had to await the study of an increased number of patients over a longer period of time.

METHOD OF STUDY

The present report summarizes the clinical experiences of the past five years during which time some 224 patients with cirrhosis of the liver were studied. The fate of these patients is compared with that of a similar control group of patients treated in the same hospital under similar circumstances prior to the use of the present therapeutic regimen.

The therapeutic regimen used in the treatment of the present series of patients is summarized in Table I.

Diet—The protein intake was maintained as near 100 Gm per day as possible so that presumably adequate supplies of methionine and cystine as well as other essential amino acids were provided. The fat intake was limited to approximately 50 Gm per day. It seemed unreasonable to burden further a fatty liver with additional supplies of fat since it was assumed and later demonstrated experimentally⁴ that under some circumstances at least much of the liver fat was exogenous in origin. Animal fat was particularly avoided since cholesterol is known to be one of the most potent stimulants to fat infiltration. Such fat infiltration is reported by some observers to be exceedingly resistant to hypotrophic agents.² Carbohydrate was given ad libitum (400 to 600 Gm) and in sufficient quantities to spare dietary protein for more essential purposes. The total caloric value of the diet was approximately 3,000 calories.

Drugs—More specific attempts were made to supply choline and methionine. At first 1 Gm of choline chloride was given daily in divided doses. Since it

TABLE I THERAPEUTIC REGIMEN

Diet	
Protein	90 100 Gm +
Fat (chiefly vegetable)	50 Gm
Carbohydrate	Adequate to supply caloric needs
Drugs	
Choline hydrochloride	1 8 Gm
Methionine (1 qt skimmed milk)	0 9 Gm +
Vitamins	
A	10,000 U S P units
D	800 U S P units
Abstinence from alcohol	

had been emphasized by some observers^{3, 5} that large doses of choline given over a prolonged period of time were required once liver damage was established, the dosage was increased cautiously on the basis of the patient's tolerance. Few were able to take more than 6 Gm, and none more than 8 Gm without experiencing gastrointestinal symptoms which were thought to be referable to the choline chloride. Most patients took and tolerated 3 to 5 Gm daily very well.

Since pure methionine was obtainable with difficulty and at a considerable cost at the outset of these observations, milk was used as a source thereof. All patients consumed at least one quart of milk (skimmed to avoid unnecessary animal fat) daily. This is equivalent to approximately 0.9 Gm of methionine.

Vitamins—Supplements of the fat-soluble vitamins A (10,000 U S P units) and D (800 U S P units) were given in order to compensate for the restrictions of dietary fat. Supplements of the B complex were not used so as not to complicate further the evaluation of the therapeutic program.

Alcohol—Alcohol consumption was prohibited, not because of any fear of the alcohol per se, but rather because the therapeutic regimen usually was followed inadequately if the patient continued to imbibe. Whenever it was apparent that cooperation in this respect was not probable, the patient was kept in the hospital for long periods of time (six to eight months) and often on repeated occasions. No similar effort was made to govern the alcohol intake of the control group. While it is difficult to evaluate the relative extent to which the members of the two groups heeded the warning to abstain, it is very probable that far better control was maintained in the experimental group.

CASE MATERIAL

Those patients admitted to the St. Louis City Hospital during the eleven year period beginning April 1, 1935, and upon whom the diagnosis of cirrhosis of the liver was made are the basis of the present report. The patients were divided into two groups—the experimental and control groups. The former included those patients with cirrhosis who were admitted to the hospital after April, 1942, and who were treated according to the therapeutic regimen described. The control group consisted of those patients who were admitted prior to April 1, 1942, and who were not treated according to any particular therapeutic regimen. For the most part these patients received a high carbohydrate diet. An occasional omentopexy was done.

Of the entire series of 647 patients, 112 were omitted from consideration in this study because of doubts concerning the validity of the diagnosis. There remained 224 patients in the experimental series and 311 patients in the control group. Autopsy or biopsy material was available on approximately 65 per cent of these patients. The remainder of the diagnoses were based upon unmistakable clinical and laboratory data. (See Table II.)

TABLE II CASE MATERIALS

	EXPERIMENTAL (4/1/42 TO 1/1/46)	CONTROL (4/1/35 TO 4/1/43)	BOTH (4/1/35 TO 4/1/46)
Total number of hospital admissions	5621	6181	12009
Diagnosis of cirrhosis	263	384	647
Diagnosis doubtful	39	73	112
Total number of patients with cirrhosis	224	311	535
Incidence (per cent of total admissions)	0.40	0.49	0.45

Although the number of patients in each of the two series was thought to be sufficiently large to insure their comparability, an effort was made to compare the two series in as many respects as possible.

The incidence of the disease among the total hospital admissions, the sex, incidence of the disease, the age of the patients, their occupations, the presenting complaints, the initial physical findings, and the laboratory data were approximately the same in the two series of patients. Because of the rationale upon which the therapeutic regimen is based, the dietary and alcoholic histories as well as the size of the livers deserve special consideration.

Alcohol Consumption—Objective data regarding alcohol consumption before admission are difficult to secure. Both the patient and the physician are likely to color the information as the result of their own past experiences. The following arbitrary classification of alcohol consumption is the basis for the present evaluation.

One plus, occasional consumption of alcoholic beverages but not to the point of intoxication, two plus, average daily consumption of one or two highballs or two to four glasses of beer, three plus, average daily consumption of a pint of hard liquor or four quarts of beer, four plus, all others.

TABLE III HISTORY OF ALCOHOLISM IN PATIENTS WITH CIRRHOSIS

	EXPERIMENTAL		CONTROL		BOTH	
	NUMBER	PER CENT	NUMBER	PER CENT	NUMBER	PER CENT
No data	33	15.5	94	60.1	127	34.4
Data	180	84.5	62	39.9	242	65.6
Total	213	100.0	156	100.0	369	100.0
Alcoholism						
Denied	12	6.7	1	1.6	13	5.4
1+	24	13.4	0	0.0	24	9.9
2+	20	11.1	3	4.8	23	9.5
3+	21	11.7	21	33.9	42	17.3
4+	103	57.7	37	59.7	140	57.9
Total	180	100.0	61	100.0	241	100.0

Most would probably agree that those characterized by three and four plus alcohol consumption should be classified as chronic alcoholics. The data presented in Table III reveal that 70 to 75 per cent of the patients in these two series were chronic alcoholics.

Dietary Histories—Accurate data on dietary habits are equally difficult to secure and must also necessarily involve subjective factors both on the part of the patient and the interrogator. Nonetheless an attempt was made to evaluate the diets in approximately half the patients. In Table IV it will be observed that 75 per cent or more of the patients were existing on inadequate food intake. Deficiencies in protein, fresh fruits, and vegetables as well as total calorie intake usually were obvious. Such deficiencies were correlated with alcohol consumption. Patients readily admitted that when they were drinking they did not eat.

TABLE IV DIETARY HISTORY OF PATIENTS WITH CIRRHOSIS

Adequate	16	15.4	0	0.0	16	13.7
Average or fair	8	7.7	0	0.0	8	6.8
Inadequate	80	76.9	13	100.0	93	79.5
Total	104	100.0	13	100.0	117	100.0

The 20 or 25 per cent of the patients whose consumption of alcohol was not considered to be excessive and whose diet was not necessarily inadequate are of considerable interest. While it is undoubtedly true that some of these individuals may have been inaccurate in relating their histories, it is equally certain that lesions of the liver indistinguishable clinically or anatomically from those of typical alcoholic cirrhosis occurred in the absence of gross dietary defects or excessive alcohol consumption. Vague histories of previous jaundice were obtained in some of these patients. Whether or not these were instances of infectious hepatitis cannot be stated with any certainty.

TABLE V LIVER SIZE

Total	100.0	100.0	100.0

*MCL, Mid-costal line.

Size of Liver—Enlargement of the liver was one of the most constant physical findings. More than 75 per cent of the patients had definitely palpable livers. In most instances the enlargement was considerable, as is evident upon inspection of Table V. It is presumed that such enlargement was the result of fat infiltration and hypertrophy of liver cells. Lipotropic substances should be of value under these circumstances.

FINDINGS

Survival—The fate of the patients in the two groups as of Oct. 1, 1947 is summarized in Table VI. One hundred sixty nine or 75.5 per cent of the experimental group were known to be dead as compared with 266 or 85.5 per cent of the control group. This comparison permits no conclusion regarding the merits of the therapeutic regimen since the period of observation for the experimental group was several years shorter than that of the control group. The observed periods of survival after the onset of initial symptoms varied from 210 to 730 months in the experimental group as compared with 780 to 1760 months in the control group. The average period of survival for the period of observation was 40.2 and 122.0 months respectively.

‡ 61.3 per cent autopsied

† 16.9 per cent autopsied

Mortality—It was not possible to utilize all these cases since the cause of death in some instances was not thought to be directly or indirectly related to the liver disease. In still other instances the lack of adequate data regarding the time of onset of the disease precluded use in this comparison. The experimental series was thus reduced to 139 patients thought to have died of liver insufficiency after a definite period of clinical disease as compared with a similar series of 197 cases in the control group. (See Table VII.)

The percentage of patients in each of the two groups dead at any given time after the onset of the initial symptoms is compared graphically in Fig. 1. No difference between the two groups of patients is apparent. The maximum

TABLE VII SELECTION OF CASES FOR STUDY

known period of survival in the experimental group to date is slightly less than six years as compared with more than sixteen years in the control group

A definite time (within a month) of onset of ascites was elicited in 100 instances in the experimental group and in 154 instances in the control group

Fig 1

Fig 2

The percentage of patients dead at any given time after the onset of ascites is compared for the two groups in Fig 2. The results are in no wise different from those described in the preceding paragraph.

A clear cut history of the onset of jaundice thought to be associated with the patient's cirrhosis, was elicited in forty six experimental subjects and in sixty three control patients. It is of interest that several patients gave a history of jaundice ten or more years prior to the obvious onset of cirrhosis.

Fig. 3

Fig. 4

Such attacks of jaundice were not interpreted as heralding the onset of the patient's cirrhosis. The percentage of patients of the two groups of patients known to be dead at various times after the onset of jaundice is compared in Fig. 3. Again there is no basis for assuming any difference in the life expectancy of individuals in the two groups.

Finally, the percentage of patients dead at various intervals after the onset of gastrointestinal bleeding is compared in Fig. 4. The number of patients available for comparison was markedly less than in the previously described groups—twenty-one in the experimental group and thirty-seven in the control group. It will be noted that the treated group fared less well than the control group. Since more than half of the treated patients were dead in less than two months it is hardly reasonable to assume that therapy could have had any influence on these patients.

COMMENT

It is clear that in spite of preferential treatment with regard to supervision and follow-up care, the experimental group fared no better than the control group so far as survival is concerned. Several possible explanations for the failure of the therapeutic regimen to prolong life deserve consideration.

- (1) The regimen was not adequately followed by the patients.
- (2) The disease was so far advanced as not to be amenable to therapy.
- (3) The therapeutic regimen was inadequate in one or more respects.
- (4) Initial liver damage, possibly by factors other than dietary defects, had rendered the organ incapable of utilizing the materials supplied.

(1) Since 60 to 75 per cent of the patients in this series were chronic alcoholics it is probable that difficulty was encountered in enforcing the therapeutic regimen when the patients were not under observation in the hospital. In addition it is important to point out that many of these patients were without adequate resources for the purchase of food and other essentials. To avoid this difficulty, as previously indicated, prolonged hospitalization was utilized freely. Attempts at the evaluation of the adequacy of therapy in individual cases was made but was found to be impracticable.

(2) Evaluation of the stage of the patient's disease was also difficult. The size of the liver is ordinarily considered to decrease as the cirrhosis advances. This we found was not strictly true. A large percentage (70 to 75 per cent) of the patients studied, however, did have definite hepatic enlargement suggesting hypertrophy and/or fat infiltration. Such patients may reasonably be expected to respond more quickly and adequately than those with small, hard, intensely fibrosed livers.

(3) Analysis of the therapeutic regimen in the light of clinical and laboratory observations of the past few years suggests some desirable changes. The importance of supplying adequate amounts of an adequate variety of amino acids should be emphasized. The patient with cirrhosis is invariably suffering from depletion of tissue protein as well as blood protein. The keen competition for individual amino acids that may ensue under such circumstances by a multiplicity of body processes is well known. Fat transport and utilization as well as repair of damaged liver parenchyma are at the mercy of the amino acid supply.

The amino acid supply may be influenced profoundly by the presence of pancreatic disease, edema or atrophy of the intestinal tract, and the palatability

of the diet (fat content) These obstacles may be at least partially overcome by supplementing the oral consumption of protein with parenteral amino acids, at least at the onset of therapy

Some doubt may be cast upon the wisdom of strict limitation of the fat intake The relative importance of deficiencies of the essential fatty acids, excessive cholesterol intake, and adverse effect upon the protein intake cannot be decided readily The great importance of protein would certainly argue in favor of considerably more freedom in the fat intake than has been permitted in this therapeutic experiment so as to assure optimal protein intake

Only a limited number of studies are available upon which one might base any accurate statements regarding choline requirements or tolerance in man It is known that the requirement is influenced by other dietary factors that is protein (methionine cystine), growth, and so forth Assuming the requirement in man to be comparable to that in the dog or rat or chick it is reasonable to assume that the human requirement is near 15 to 30 Gm daily¹ The average diet of man contains 15 to 40 Gm daily¹ If the toxic effect of choline on man is comparable to that experienced by chicks and mice man would be expected to experience minimal toxic effects from 15 to 20 Gm of choline daily¹ Assuming the daily diet of the patients studied to have contained 40 Gm of choline, even with the maximum dose used (8 Gm) no toxic manifestations would have been anticipated It is possible that a marked increase in choline dosage is indicated since Kaplan and Chaikoff state that as much as 3 Gm of choline daily are required to cure fatty livers in dogs if such fat infiltration is permitted to develop³ Upon the basis of body weight this is comparable to doses of 15 to 30 Gm daily in a human being weighing 60 kilograms Much of the animal experimentation has been preventive rather than curative and is of little value in determining the dose needed in the treatment of human beings with established liver lesions

The methionine requirement is probably influenced by other dietary factors growth and so forth as is the choline requirement Very little specific information is available to guide one in the matter of dosage

While the use of supplements of the B complex (brewers yeast crude liver extracts, and so on) was avoided in the treatment of the series of patients described, there can be no doubt that such supplements are indicated in view of the multiple evidences of malnutrition observed in patients with cirrhosis Aside from the correction of multiple specific deficiencies, the salutary effect upon the patient's appetite is of extreme value It was reasoned that mobilization of liver fat would be attended by improvement in appetite, and relief of specific deficiencies by the ingestion of an adequate diet This may be true but valuable time may be lost at a critical stage in the patient's illness

(4) Primary damage to the liver may so impair its ability to discharge its responsibilities for fat metabolism that a fatty liver will ensue no matter how adequate the supply of dietary essentials may be Such primary damage might be produced by many agents or methods Experimentally phosphorus or carbon tetrachloride may produce such impairment of function even though accompanied by or preceded by the use of lipotropic factors If the influence of the

noxious agent is eliminated and enthusiastic therapy begun, the damage may be reversible. Unrecognized or inadequately treated damage of this sort in the human subject may be very difficult or impossible to treat successfully when it ultimately comes to the attention of the clinician.

CONCLUSIONS

Low fat diets supplemented by 1 to 8 Gm of choline and one quart of skimmed milk daily (0.9 Gm methionine) failed to influence the life span of patients with cirrhosis of the liver, even though these patients were much more closely supervised than the control series.

DISTRIBUTION OF GOLD IN THE ANIMAL BODY IN RELATION TO ARTHRITIS

J J BELTRAND, M D,* H WATF, M D † AND C A TOBIAS PH D
BERKELEY, CALIF

ALTHOUGH gold and gold salts have had wide clinical application in diseases of the skin in tuberculosis and of late in rheumatoid arthritis their mode of action is undetermined. Worth while information about the pharmacology of gold salts has been gained particularly through the application of a micro method developed by Block and Buehner¹ in the metabolic studies of Freyberg and associates as well as in the investigations by Denko and Anderson² Coitell and Richards³ and Hartung and Cotter.⁴ The following contains experimental data on the distribution of gold given as radioactive material and first used by Ely.¹¹

METHOD

Au¹⁹⁸ (half life 2.7 days) produced in a pile by the (n, γ) reaction was obtained from the Atomic Energy Commission with a specific activity of about 2.5 mc per milligram. Radioactive gold sodium thiosulfate was synthesized from the radioactive gold and administered intravenously. The tissue samples and excreta were weighed and ligated in nitric acid and hydrogen peroxide, the gold was then quantitatively removed by a process of electro deposition¹² developed by Dunn of this laboratory. The punchlets with the radioactive gold were counted by means of a bell jar Geiger Muller counter with a thin mica window. All data presented were corrected for half life.

RESULTS

The excretion of Au¹⁹⁸ was studied in two white rats. The fractions of initially administered drug excreted during the first eight days are given in Table I. After the first week excretion became very slow. Further excretion studies are now in progress.

Gold Distribution in Rats—Distribution experiments were set up using rats in which quantitative recovery of the administered gold was attempted. In these experiments all excreta were saved the gold being recovered from this and from the whole carcass (minus samples removed). When such a procedure was followed, 97.75 per cent of the total gold administered could be recovered. Duplicate samples of each tissue were taken as a further check on the accuracy of the method employed.

The discrepancies indicated for bone and synovials cannot be explained completely. In the case of synovials values tend to become higher at longer

intervals, and there is also the factor of small sampling. Synovial samples from rats average 5 to 10 mg, and small amounts of evaporation could easily account for significant weight loss in such samples. Any such error is greatly increased when data are expressed in terms of grams.

When the accuracy of the technique was ascertained by such quantitative recoveries a series of fifteen rats was employed, each rat receiving 2 ml of radiogold sodium thiosulfate solution containing 10 mg of gold and approximately 1 mc of radioactivity. The amount of radioactivity varied with the time of injection and was in all cases exactly known. The animals were sacrificed at intervals of two to eight days. Before sacrifice these animals were perfused with physiologic saline solution through the proximal end of the inferior vena cava and were bled through the distal end of the same vessel, in some cases however, the saline was introduced directly into the heart while bleeding took place through the inferior vena cava.

The agreement between respective determinations was fair in most cases; however, some organs showed considerable fluctuations in gold content—notably the kidney and spleen. The time interval had little to do with the values of

any given tissue, which would seem to indicate that gold is held rather firmly by the respective tissues once it has left the blood stream. As can be seen in Table I, the amount excreted is small after the fourth day.

Gold distribution data were taken on ten rabbits at different time intervals. Before sacrifice the rabbits were perfused with normal saline through the proximal end of the inferior vena cava and bled through the distal end of the same vessel. There was a general agreement between respective determinations although some organs showed considerable fluctuations in gold content. A typical set of the results obtained for the concentration of Au^{198} in various types of tissue is given in Table IV.

In the course of this work specific activities of several tissues were ascertained for which the uptake of gold salts had not been demonstrated previously such as the iris, aqueous and vitreous humors and brain. All these organs contained gold quantities in the order of 10^{-4} per cent of the injected amount per gram of tissue.

A comparison of the data given for rabbits and rats shows great variance which is due to the greatly increased dilution of the administered dose in the rabbit. The average weight of the rats used was 150 grams, while that of the rabbits equaled 2.5 kilograms. When correction was made for this factor the results were comparable, as can be seen in Table V.

TABLE V COMPARISON OF GOLD DISTRIBUTION IN RABBITS AND RATS

Heart	.21	.15
Muscle	.07	.03

Values expressed in per cent total dose injected per gram tissue

The similar relative order is interrupted by the synovial sample in the rat, which may be falsely high.

Gold Uptake in Chemical Synovitis—Chemical arthritis was produced in five rabbits by the intra-articular injection of 0.5 cc of a solution, composed of U. S. P. turpentine 3 parts and diethylether 1 part, into the knee joint of one extremity. This was repeated in five days. Ten days after the initial injection the animals were given the radiogold thiosulfate by the intravenous route, and five days later the rabbits were sacrificed for assay after first being perfused with 0.89 per cent saline. The rabbits had not been walking since twenty-four hours following the initial treatment. The joints were swollen to twice the normal size and were tender and hot to the touch.

On autopsy the synovialis showed proliferation to a moderate degree and the articular surfaces were dull and roughened.

As can be seen from Table VI, in all cases the chemically inflamed tissues took up a significantly larger amount of gold salt than the normal tissue. From previous experience with the distribution of gold in the blood components it was known that the white blood cells contained considerable amounts of thiosulfate, and it was thought that this fact might account for the higher level in

Rabbits were given 15 mc ten days after turpentine injection. Values are expressed in per cent total dose per gram tissue.

P and N refer to pathologic and normal respectively.

the inflamed tissues, however pure pus from sterile abscesses was found to have less activity per gram than the tissues under consideration and in tissues such as bone and tendon large exudative responses were not noted. It was clear from this that even though the inflammatory elements might be responsible for part of the concentration they could not possibly account for all and that in the presence of inflammation the tissues themselves soaked up more of this salt.

In view of these facts we wondered about the specificity of this phenomena for joint structures. It was found that apparently the reaction would occur outside of joints, for when the same chemical mutant was injected into muscle and a sterile abscess formed the muscle wall of the abscess would also accumulate the salt. This perhaps makes the accumulation in the joints less noteworthy but nonetheless real.

Human Experimentation—It was possible* to carry out a preliminary distribution experiment on a human arthritic subject. The patient selected was a 57 year old white woman with rheumatoid arthritis of a moderately advanced stage and of approximately ten years duration. Pain upon motion was present in both knees; movement was only slightly restricted. The patient had never received x-ray therapy. She was given 1010 microcuries of radiogold as the sodium thiosulfate salt representing 25 mg of gold. Twenty-four hours after administration, biopsy of the left knee was done; specimens of skin, superficial fascia and fat, deep fascia and fat, synovial fluid, synovial membrane and muscle were taken. Of the tissues taken the synovials was by far the most active with the synovial fluid next in activity. This indicates that in human beings with rheumatoid arthritis the synovials is at least somewhat of a concentrator of gold.

TABLE VII GOLD DISTRIBUTION IN RHEUMATOID ARTHRITIS

Synovials	014
Synovial fluid	0094
Muscle	0013
Superficial fascia	000366
Deep fascia	000596
Skin	00074

It is interesting to note that the synovials is eighteen times higher in gold content than skin. If we compare the gold concentrating ability of human and rat skin the value (014 per cent) for synovials is in the range one would expect for kidney—18 times 47 (rat skin) equals 846 (value for rat kidney).

CONCLUSIONS

Au^{198} is a suitable radioactive isotope for studying the action of gold on the animal body. Excretion and distribution data obtained with this isotope

*Through the cooperation of Professor William J. Kerr, Chairman, Department of Medicine, University of California Medical School.

conform with previous observations using stable gold. Synovials, tendon, and articular cortex in chemical arthritis show a greater uptake of gold than similar tissues of normal joints, and this was shown to be nonspecific since the muscle wall of sterile abscesses exhibits the same phenomenon. Passage of gold from the blood stream into the central nervous system and ocular structures of rabbits has been demonstrated.

THE EFFECT OF NUTRITION ON THE TUMOR RESPONSE IN ROUS CHICKEN SARCOMA

PAUL A. LITTLE, M.S., J. J. OLESON, PH.D., AND Y. SUBBAROW, PH.D.
PEARL RIVER, N. Y.

INTRODUCTION

NUMEROUS observations have confirmed the fact that nutrition may influence the genesis and growth of tumors in rats and mice. The search for requirements in the nutrition of malignant tissue should reveal findings that are valid regardless of the nature of the tumor studied or the kind of animal used as well as more limited findings. Such information might well include the facts that adequate calorie intake has been shown necessary for tumor growth¹ and that vitamins such as pantothenic acid and riboflavin have been found stimulative² whereas choline may be inhibitory.³

EFFECT OF NUTRITION IN ROUS SARCOMA

Little and co-workers⁴ showed that folic acid has a marked effect on the tumor response in Rous chicken sarcoma. The effectiveness of folic acid free diets in preventing the tumor response of baby chicks and the rapidity and regularity with which the response occurred in adequately nourished chicks led us to our present study of the effect of each of the different constituents in a synthetic diet for chickens.

The data to be presented confirm observations made on rats and mice to the effect that malignant tissue may utilize vitamins such as pantothenic acid and riboflavin for growth. Our results also indicate that nicotinamide and choline acid may be stimulative. However, folic acid appears to be the only nutrient required to the extent that tumor response is prevented by its absence.

Method for Demonstrating the Effect of Nutrition—In our tests the extent to which each nutrient influenced tumor response was determined by comparing the incidence of tumors in groups of chicks fed the complete diet with the incidence of tumors in groups fed the same diet without the nutrient. By comparing observations made on the eighth, tenth, twelfth, fourteenth, and sixteenth day the effect of nutrition was evaluated for all stages from the usual time of first appearance of tumors to the time when 90 to 100 per cent of control birds showed tumors. The response with and without nutrient was calculated from the combined results of different tests where more than one test was carried out. The percentage of birds showing tumors when fed diets with the nutrient was divided by the percentage showing tumors when fed the same diet without the nutrient. The nutrients which showed no stimulative effect gave values of approximately 1.0.

Relation of Size of Inoculum to Tumor Response—An even distribution of tumor response over the eight days selected for observation of results was readily obtained by controlling the size of the inoculum. As shown in Table I, there is a direct correlation between the size of inoculum and the length of the latent period.

We used homogeneous amples of frozen virus prepared by blending fresh tumor tissue in a Waring mixer and weighing 2 Gm. amounts into sterile Petri plates to be stored in a dry

ice chest until used. Preliminary suspensions containing 10 mg in a 0.25 ml dose were prepared by adding 50 ml of 2 per cent peptone solution to 2 Gm of tumor tissue. A Ten Brock grinder was employed, and further dilutions were made in peptone solution.

In our experiments the desired length of latent period was obtained with 1 mg of inoculum. The frozen virus was found to be stable for at least a month. It is of interest that Reinhard and co-workers⁵ found a similar relationship between the size of inoculum and the length of the latent period for growth of a transplantable mouse adenocarcinoma.

One day old New Hampshire Red chicks which were the progeny of a selected flock (as described in our previous report⁴) were injected in the right breast with 0.25 ml of the suspension containing the 1 mg dose. The feathers were removed from the breast area before inoculation. Groups of ten birds were placed on diets with and without each nutrient tested. Nutrients which were of interest because of possible stimulative effect were retested several times. The chicks were maintained in electric brooders at 90° F, water and food were supplied ad libitum. Approximately 400 chicks (ten to twenty per group) were used in each experiment.

The basal diet contained 53 per cent Cerelose,* 22 per cent alcohol extracted casein, 4.3 per cent salt mixture, 3 per cent calcium gluconate, 8 per cent gelatin, 4 per cent Ruffin,† 3 per cent soybean oil, 0.25 per cent cholic acid, 0.45 per cent cystine, 200 mg per cent choline chloride, 3 mg per cent calcium pantothenate, 3 mg per cent nicotinamide, 0.5 mg per cent pyridoxine, 0.3 mg per cent thiamin chloride, 0.03 mg per cent biotin, 0.5 mg per cent riboflavin, 100 mg per cent inositol, 5 mg per cent para-aminobenzoic acid, 0.2 mg per cent folic acid, 5 mg per cent vitamin E, 0.2 mg per cent vitamin K, 3,500 units per cent vitamin A, and 200 units per cent vitamin D. The diet with nutrient was usually the complete diet. A commercial chick starter gave the same tumor response as the complete synthetic diet. In studies of substitutes for soybean oil, the diet with nutrient contained the substitute and the basal diet was soybean oil free. In these tests the vitamins A, D, E, and K were added in propylene glycol.

The chicks were observed daily beginning with the eighth day and continuing through the sixteenth day at which time adequately nourished groups showed 90 to 100 per cent tumors. Wing tags applied on the sixth or seventh day were used to identify individual birds. The increasing sizes of tumor were recorded (as previously described) for evidence as to the accuracy of first observations. Tumors recorded as questionable were counted in determining the response whenever this observation was confirmed by subsequent findings.

†Purified cellulose containing 70 per cent α cellulose and 30 per cent other cellulose. Fisher Scientific Co. Pittsburgh Pa.

EXPERIMENTAL RESULTS

Three distinct types of results have been obtained with nutrients which demonstrated a definite stimulative action on tumor growth. While with and without values of approximately 10 were obtained in tests on nutrients which did not stimulate tumor growth (A) constant values of approximately 30 were obtained in tests of riboflavin, (B) descending values of 13.0, 6.2, 4.6, 2.6, 2.1 were obtained in tests of nicotinamide and (C) ascending values of 13.0, 40.0, 63.0, 89.0, 93.0 were obtained in tests of folic acid. While other nutrients gave results similar to those illustrated in A and B, folic acid was the only nutrient giving the result C.

The Effect of Vitamins From Liver—Table II shows the effect of nine water soluble vitamins on the tumor response of chicks to Rous sarcoma virus. Folic acid produced the greatest effect and para aminobenzoic acid and biotin produced the least effect. Nicotinamide and calcium pantothenate influenced the rate of growth more than the final incidence; riboflavin did not change the rate of growth but did influence the incidence at all stages.

TABLE II EFFECT OF WATER SOLUBLE VITAMINS IN DIET ON ROUS SARCOMA (RATIO OF PER CENT INCIDENCE ON THE COMPLETE DIET TO PER CENT INCIDENCE ON THE DEFICIENT DIET)

VITAMIN	AMOUNT IN DIET	NUMBER OF CHICKS (A/B) ^a	NUMBER OF TESTS	RESPONSE WITH VITAMIN				
				RESPONSE WITHOUT VITAMIN				
				8	10	12	14	16
Thiamin	3 mg/kg	10/10	1	30.0	1.5	1.3	1.1	1.1
Riboflavin	5 mg/kg	39/37	4	2.1	3.0	3.1	3.1	3.1
Pyridoxine	5 mg/kg	30/30	3	2.0	2.9	1.8	1.4	1.3
Nicotinamide	30 mg/kg	29/29	3	13.0	6.2	4.6	2.6	2.1
Calcium pantothenate*	30 mg/kg	29/18	3	24.0	11.0	2.6	2.0	1.8
Inositol	1 Gm/kg	29/25	3	13.0	1.2	1.1	1.0	1.0
Para aminobenzoic acid	50 mg/kg	19/19	2	1.4	1.1	1.0	0.8	0.8
Biotin	0.3 mg/kg	29/27	3	1.1	1.8	1.2	1.1	1.1
Folic acid	2 mg/kg	30/32	3	13.0	40.0	63.0	89.0	93.0

^a Vitamin deficient chicks were revived with complete diet beginning on the tenth day.
^b Total chicks used to determine effect of diets (a) with and (b) without the vitamin specified.

Since deficiencies of thiamin, pyridoxine and calcium pantothenate caused serious loss of weight, chicks fed diets without these vitamins were revived with complete diet beginning on the tenth day. In previous work with folic acid it had been shown that the stimulative effect of restoring this vitamin on the tenth day does not become apparent for at least seven days. This practice was adopted in the case of thiamin, pyridoxine and calcium pantothenate deficiencies to permit survival of the birds for the duration of the test. The responses with and without one of these vitamins for the twelfth, fourteenth and sixteenth day may or may not be influenced by restoring the vitamin on the tenth day.

Since liver is a rich source of still unidentified vitamins, several fractions of liver were tested in the presence of the nine purified vitamins for possible stimulative effect on the tumor response of chicks to Rous sarcoma virus. None of the liver fractions influenced the rate of growth or incidence of tumor to an extent which would indicate the presence of additional factors for tumor growth.

The Effect of Vitamins A, D, E, and K—The results of tests of diets with and without vitamins A, D, E, and K are shown in Table III. None of these vitamins stimulated tumor growth when present in the diet. The values 0.8, 0.6, and 0.5 suggest that the oil-soluble vitamins may slightly retard tumor growth. It is of interest that diets with and without the combination of soybean oil and vitamins A, D, E, and K influenced the tumor response to a greater extent than did the diets with and/or without the oil-soluble vitamins alone.

TABLE III. EFFECT OF OIL SOLUBLE VITAMINS IN DIET ON ROUS SARCOMA (RATIO OF PER CENT INCIDENCE ON THE COMPLETE DIET TO PER CENT INCIDENCE ON THE DEFICIENT DIET)

VITAMIN	AMOUNT IN DIET	NUMBER OF CHICKS (A/B*)	NUMBER OF TESTS	RESPONSE WITH VITAMIN				
				RESPONSE WITHOUT VITAMIN				
				8	10	12	14	16
Combined A	35,000 I U/kg							
D	2,000 I U/kg	19/19	2	0.8	1.0	1.0	1.0	1.0

*A/B Total chicks used to determine effect of diets (A) with and (B) without the vitamin specified.

The Effect of Various Fats and Oils—Table IV shows the results of tests in which twelve different substances were tested in a soybean oil free diet. None of these substances stimulated tumor growth. Soybean lecithin, cod liver oil, and linoleic acid appeared to retard tumor growth when present in the diet. Most of the other substances in the group showed this effect to some degree.

TABLE IV. EFFECT OF FATS AND OILS IN DIET ON ROUS SARCOMA (RATIO OF PER CENT INCIDENCE ON THE COMPLETE DIET TO PER CENT INCIDENCE ON THE DEFICIENT DIET)

a/b Total chicks used to determine effect of diet (a) with and (b) without the substance specified

SUMMARY

The effect of nutrition on the tumor response in Rous chicken sarcoma was determined by comparing observations of chicks fed synthetic diets with and without each nutrient. Tumor response was stimulated by the presence of folic acid, nicotinamide, calcium pantothenate, riboflavin, and cholic acid in the diet. Folic acid was the only nutrient required to the extent that tumor response was prevented by its absence from the diet.

THE USE OF ANTAGONISTS OF PTEROYLGLUTAMIC ACID IN CONTROLLING ROUS CHICKEN SARCOMA

PAUL A. LITTLE, M.S., ANGUS SAMPATH, AND Y. SUBBAROW, PH.D.
PEARL RIVER, N. Y.

SINCE Woods¹ described the interference of *p*-aminobenzoic acid on the action of sulfonamides, the antagonism between compounds promoting growth and those which inhibit growth has received increasing attention. Analogues of pteroylglutamic acid (folic acid) have been studied extensively. The antagonistic activity of these compounds in the growth of *Streptococcus faecalis* R has been examined by Hutchings and Stokstad.² Experiments leading to the demonstration of a stimulatory effect of pteroylglutamic acid and an inhibitory effect of its antagonists on Rous chicken sarcoma have been reported by Little and co-workers³ and by Woll.⁵

In the present report we wish to present more recent findings with regard to the effect of choice of antagonists and method of administration on the outcome of experiments with Rous chicken sarcoma. Table I contains a list of the antagonists of pteroylglutamic acid which we have tested for ability to control Rous chicken sarcoma. Both the abbreviated names of compounds (such as used in our first report on Rous sarcoma) and the complete chemical names are shown as an aid in referring to reports dealing with the synthesis of these compounds. The antagonists which we have found most useful, for reasons to be discussed, are the 4-amino-pteroylaspartic acid and the 4-amino-pteroyl(γ)glutamic acid which were synthesized by Mowat and others,^{10*} and the 4-amino-pteroylglutamic acid synthesized by Seeger, Smith, and Hultquist.[†]

PROCEDURE

In producing Rous chicken sarcoma we have employed homogeneous samples of frozen virus prepared by blending fresh tumor tissue in a Waring mixer and weighing 2 Gm. amounts into sterile Petri plates to be stored in a dry ice chest until used. Preliminary suspensions containing 10 mg. in a 0.25 ml. dose were prepared by adding 50 ml. of 2 per cent peptone solution to 2 Gm. of tumor tissue. A Ten Broeck grinder was employed, and further dilutions were made in peptone solution. The size of inoculum used in our experiments was determined by titration of the virus for even distribution of tumor responses over a period of time from the eighth to the sixteenth day of the test. The frozen virus was found to be stable for at least a month with respect to the effect of concentration of virus on the time distribution of tumor responses. Table II illustrates the method employed for standardizing the virus.

HANDLING OF CHICKS

New Hampshire Red chicks which were the progeny of a selected flock (as described in our previous report)⁴ were injected in the right breast with 0.25 ml. of the suspension containing the dose required for the desired distribution of tumor responses. The feathers were removed from the breast area before inoculation. Groups of ten birds were compared with

1 mg*	140	14	14	90	98	91
100 µg	140	14	0	6	26	71
10 µg	140	14	0	1	3	31

This amount of virus gave the desired distribution of tumor responses

as many untreated controls. The chicks were maintained in electric brooders at 90° F. water and food were supplied ad libitum. Baby chicks varying from 1 to 9 days old were tested for ability to resist the toxic effect of different antagonists of folic acid.

A daily record of observations was made from the eighth day of the test to the twentieth day. The growth of tumors from the time of first appearance was recorded in the manner previously described. This information enabled us to demonstrate retardation of tumor growth when inadequate doses of antagonists were used. In the table presented in this paper, chicks showing the slightest evidence of tumor have been counted in with those showing the usual tumor response characteristic of untreated groups.

EXPERIMENTAL RESULTS

Table III shows the results of experiments with 4-amino pteroylaspartic acid. This antagonist of folic acid was administered (1) by daily intraperitoneal injection to chicks which were 2 days old at the start, (2) by daily intraperitoneal injection to chicks which were 8 days old at the start and (3) by feeding to chicks which were only 1 day old at the start. It is apparent from Table III that under the conditions in (1) the toxicity of the chemical for the chicks interfered with its value as an inhibitor of tumor growth. Under the conditions in (2) the chicks were more resistant to the toxic effect of doses inhibitory to tumor growth. Under the conditions in (3), chicks only 1 day old at the start could

be treated successfully with 80 mg of 4 amino pteroylaspartic acid per kilogram of diet without toxic effect. The diet was the regular commercial chick ration.

Table IV shows that similar results were obtained with 4 amino pteroyl d() glutamic acid. Daily injections of the doses of chemical required to inhibit tumor growth resulted in unimpairment of health and eventual loss of birds when the chicks were 2 to 3 days old at the start. Chicks 8 days old at the start showed greater resistance to the toxic effects of doses inhibitory to tumor growth. Chicks only 1 day old at the start showed no toxic effect when fed 80 mg of 4 amino-pteroyl d() glutamic acid per kilogram of diet.

Table V shows that 4 amino pteroylglutamic acid (4 amino folic acid)⁴ is suitable for use in the treatment of adult birds only. In a series of experiments we succeeded in neutralizing the toxicity of 4 amino pteroylglutamic acid for baby chicks by giving simultaneous injections of pteroylglutamic, pteroyl diglutamic or pteroyltriglutamic acid. It was found that 0.25 mg doses of pteroylglutamic acid protected 60 per cent of chicks, 0.25 mg doses of pteroyl triglutamic acid protected 50 per cent of chicks and 0.25 mg doses of pteroyl diglutamic acid protected 10 per cent of chicks against the toxic effect of 0.01 mg doses of 4 amino pteroylglutamic acid. This antagonist did not prevent tumor growth in baby chicks thus protected from its toxic effect.

Table VI shows the results of experiments with 4 amino N methyl pteroyl glutamic acid. When administered to baby chicks by daily intraperitoneal injection, this antagonist demonstrated toxicity and also inhibited tumor growth. It was not administered in the diet because of lack of material. The toxicity of 4 amino-N methyl pteroylglutamic acid appears to be similar to that of 4-amino pteroylaspartic acid and 4 amino pteroyl d() glutamic acid. These antagonists when injected produce symptoms resembling those caused by maintaining chicks on folic acid free diets. We have found that chicks showing severe symptoms as a result of injection with these antagonists quickly revive when treatment is discontinued.

DISCUSSION

It is evident from our experiments that Rous chicken sarcoma may be controlled by regulating the amount of pteroylglutamic acid in the tissues of the chicken either by use of synthetic folic acid free diets⁴ or by use of suitable

chemical antagonists. Severe deficiencies of the vitamin, whether caused by lack of folic acid in the diet or by the injection of powerful antagonists such as 4-amino-pteroylglutamic acid, regularly result in death of birds. It is well known that the amount of folic acid required to maintain the normal health of chickens is relatively small. According to Oleson¹¹ 0.5 mg per kilogram of diet is suboptimum, 1 to 2 mg are optimum, and 2 to 5 mg are superoptimum.

Our experiments indicate that at least two of the chemical antagonists of folic acid (4-amino-pteroylaspartic acid and 4-amino-pteroyl-d(-)glutamic acid) and possibly a third (4-amino-N-methyl-pteroylglutamic acid) may be appropriate tools for controlling the amount of folic acid available in the body for tumor growth without depriving the body of the amounts of vitamin required for normal health. When the treated animal is a rapidly growing chick, these chemicals appear to be more serviceable than 4-amino-pteroylglutamic acid. When the treated animal is an adult chicken, 4-amino-pteroylglutamic acid is not only serviceable, but may well be the chemical of choice inasmuch as it is effective in small doses.

The toxicity of these chemicals appears to be due solely to the severity of the vitamin deficiency which may result from too intensive treatment. Our experiments indicate that treatment by mouth is the method of choice, since tumor growth may be inhibited by this method in a greater percentage of animals without toxic effect. Evidently the tumors of Rous Chicken sarcoma are more directly dependent for their growth on the folic acid furnished by the diet than are the normal tissues of the chick. Since chicks do not develop severe deficiencies of the vitamin in the time required to demonstrate inhibition of tumor growth by use of folic acid free diets (as shown in our previous report),⁴ it is possible that the health of such chicks is protected by stores of the vitamin which are not available to tumors of this type. If such is the case, the most desirable method of treatment would be the administration in the diet of chemicals which would antagonize the vitamin present in food. We have shown that 4-amino-pteroylaspartic acid and 4-amino-pteroyl-d(-)glutamic acid can produce this result.

SUMMARY

Two chemical antagonists of pteroylglutamic acid (4-amino-pteroylaspartic acid and 4-amino-pteroyl-d(-)glutamic acid) have been found capable of inhibiting tumor growth in baby chicks inoculated with Rous sarcoma virus when the chemicals were fed *ad libitum* at a concentration of 80 mg per kilogram of diet. These chemicals and also 4-amino-N-methyl-pteroylglutamic acid were active in inhibiting tumor growth in baby chicks when injected. Toxic effects resembling the effect of severe vitamin deficiency occurred when the chemicals were injected, but not when the chemicals were fed.

TREATMENT OF THE TYPHOID CARRIER STATE

TRIAL OF TWO CHEMOTHERAPEUTIC PROCEDURES

ROBERT F. KORN, M.D., AND RAY E. TRUSSELL, M.D.
ALBANY, N. Y.

ALTHOUGH the medical literature contains many reports of unsuccessful attempts to clear up the chronic typhoid carrier state by the use of chemotherapeutic agents, it nevertheless is deemed worth while to record the results of the two studies presented here since they represent failures to confirm previously published favorable reports.

Although typhoid fever in New York State exclusive of New York City is rapidly reaching the vanishing point (fifty-two cases reported in 1947), the residual chronic carriers living in the state continue to offer the threat of further outbreaks of the disease. A total of 465 known chronic carriers are listed on the roster of the New York State Department of Health, and it is estimated that some 2,500 carriers actually survive in the state at the present time.¹ A chemotherapeutic agent effective in clearing up the typhoid carrier state would thus be a real boon to public health as well as to the individual carriers involved.

Trial of Tin Compound in the Treatment of Typhoid Carriers—The report by Reitler and Marberg² presenting apparently clear-cut evidence of therapeutic benefits afforded by a tin compound (heptadekylaldehyde stannoxysterate) in the treatment of typhoid fever and, more specifically, in the cure of two typhoid carriers seemed to warrant further clinical trial of the compound. Supplemental information³ indicated that three of four definitely proved chronic typhoid carriers were cleared of their carrier condition by administration of this drug. Accordingly in December, 1944, twenty-one chronic typhoid carriers, inmates of two New York State mental hospitals,* were selected for treatment. Preliminary stool examinations† of the carriers established the persistence and constancy of their carrier status. They were then treated with successive courses of this tin preparation‡ according to the schedule suggested by Reitler.²§ Pertinent data concerning the carriers utilized in this and the subsequent study are presented in Table I. In Fig. 1 are illustrated the time schedule of therapy and the results of stool examination.

It will be noted that none of the established carriers were cleared even temporarily of typhoid bacilli. Carrier 3, who appears to be an exception, evidently recovered spontaneously before treatment was started. Carriers 5, 9, and 16 demonstrated intermittency in their carrier condition, but this characteristic

¹From the Bureau of Communicable Disease Control, New York State Department of Health.

²Received for publication May 19, 1948.

*Willard and Harlem Valley State Hospitals.

†All bacteriologic examinations in these studies were performed at the Division of Laboratories and Research, New York State Department of Health.

‡The drug used was kindly furnished by the firm Chemica Ltd., Haifa, Palestine, who markets the drug under the trade name Aldestan.

§Each course consisted of the daily administration by mouth of ten tablets (0.02 Gm. of active ingredient per tablet) for ten days followed by a rest period of one week.

*These carriers also were treated with penicillin and sulfathiazole in a subsequent study described below

†These individuals were shown to be still carrying *Bacillus typhosus* two and one half years after the study

existed before treatment was started. Routine blood and urine examinations were carried out periodically on these carriers throughout the course of treatment in order to determine whether the drug was producing any untoward reactions but no significant difficulties were encountered.

The value of this procedure in curing typhoid carriers was given a severe test since, for the most part, it could be shown that these individuals were carriers of long duration, even though the mental status of the patients precluded the getting of a history of typhoid fever in all but four instances. Cholecystectomy had not been performed on any of the group. X-ray studies of four of the carriers indicated that either gall stones were present or that the gall bladder functioned poorly. Nevertheless, on the basis on these findings one can hardly attribute any benefit to this therapeutic procedure.

Trial of Penicillin Plus Sulfathiazole in the Treatment of Typhoid Carriers—The report by Bigger⁴ demonstrating the existence of the synergistic effect of sulfathiazole and penicillin on *Escherichia typhosa* in vitro, led to the clinical trial of these drugs by Comerford and co-workers in the treatment of two typhoid carriers. This carefully planned study seemed to demonstrate beyond doubt the cure of these carriers, both through the prompt disappearance of typhoid bacilli from the stools during the course of treatment and the continued

absence of these organisms in daily stool cultures for six months thereafter when the study was terminated. In addition, a striking drop in the typhoid Vi antibody titer of the blood occurred over this period of time. The only reservation one might have concerning the results of this work is that one of the two carriers studied was convalescent from typhoid fever and had carried the organism for only one year, and the other was a chronic carrier who persisted in excreting typhoid bacilli in the stool for ten months following cholecystectomy. Thus neither case was typical of the usual chronic typhoid carrier of long standing with a markedly sclerosed gall bladder containing stones, and it seemed possible that the course of treatment outlined would be ineffective in eradicating the infection in such individuals. Nevertheless, this therapeutic technique appeared to warrant further trial. Since that time an additional paper⁶ has reported apparent success in curing a single typhoid carrier with massive doses of penicillin alone.

■ THESE CARRIERS WERE FOUND TO STILL HAVE E. TYPHOSA IN THE STOOLS TWO YEARS LATER

Fig 1—Treatment of typhoid carriers with tin compound schedule of therapy and results of stool examinations

The schedule of therapy utilized by Comerford and co workers was dictated by in vitro studies which demonstrated the optimal concentrations of sulfathiazole and penicillin needed for inhibition and destruction of the typhoid bacillus. With slight modification, the same schedule was utilized in the present study.

A total of eight chronic carriers, inmates of New York State mental hospitals,* were utilized in this study which was started in August, 1947. (This

*Willard and Harlem Valley State Hospitals

series represents Carriers 6, 8, 11, 12, 13, 14, 15, and 21 of the first study) Accumulated records indicated the long time chronic nature of their carrier state Daily stool specimens for a period of ten days prior to initiation of treatment confirmed the persistence of the carrier state and the constancy of positive stool findings None of these individuals were urinary carriers For an eight day period sulfathiazole was given by mouth 1 Gm every four hours, and crystalline sodium penicillin, in doses of 1 000 000 units was administered intramuscularly every six hours Studies of the penicillin blood level* showed uniformly high levels of penicillin one half hour after administration of the drug which reached a peak of 61 units per milliliter of blood during the fifth day of treatment Samples collected immediately before successive doses were administered showed at all times more than 0.49 unit of penicillin per milliliter The results of bacteriologic examination of the stools from these carriers before, during, and subsequent to treatment are illustrated in Fig 2

Fig 2—Treatment of typhoid carriers with penicillin and sulfathiazole record of stool examinations and schedule of therapy

Other pertinent data concerning these carriers already have been presented in Table I. It is evident that in each instance typhoid bacilli disappeared completely from the stool for a period. In two instances careful study failed to reveal their presence for several weeks after completion of the course of treatment. However, the organisms reappeared subsequently and hence in no instance was a carrier actually cured. Several of these individuals had been shown previously to have gall stones thus accounting perhaps for some of the difficulties in eradicating the infection.

Although none of the carriers treated in this study were permanently cured it is possible that this therapeutic procedure might have some application in the treatment of the typhoid carrier state which persists occasionally following cholecystectomy or in eradicating the carrier condition early in its development in convalescent cases of typhoid fever. However, it is doubtful that the procedure outlined would be effective in curing the infection in the

*These tests were performed in the laboratory of Dr George A. Taplin University of Rochester Rochester N. Y.

average chronic carrier, although more prolonged therapy with larger doses of the two drugs might be more fruitful. These findings with respect to the effect of penicillin plus sulfathiazole on *E typhosa* are in keeping with those reported by Hardy⁷ who observed a similar bacteriostatic action on *E typhosa* with sulfadiazine in nineteen chronic typhoid carriers. It would seem that the only therapeutic measure of proved value for the eradication of the typhoid carrier state is that of cholecystectomy. Experience in New York State⁸ indicates that in 68 per cent of chronic carriers undergoing cholecystectomy cure was obtained.

SUMMARY AND CONCLUSIONS

Treatment of twenty-one chronic typhoid carriers with the tin compound heptadekylaldehyde stannoxystearate (Aldestan) failed to demonstrate any effect on the presence of *E typhosa* in the stool.

The administration of penicillin and sulfathiazole to eight chronic typhoid carriers caused the disappearance of typhoid bacilli from the stool in each individual. In two instances the organisms were absent for at least two weeks following discontinuance of treatment. However, they reappeared in the stool of all the carriers.

The authors would like to acknowledge the cooperation of Dr. Kenneth Keill, Superintendent, Willard State Hospital, and Dr. Alfred M. Stanley, Superintendent, Harlem Valley State Hospital, in making these studies possible.

THE OCCURRENCE OF *SALMONELLA* BLEGDAM IN LOUISIANA*

REBECCA A. HOLT, M.A.,† and HAZEL NEWTON, M.T.‡
NEW ORLEANS, LA.

SALMONELLA blegdam was first isolated in 1929 at State Serum Institute¹ Copenhagen, Denmark, from the blood of a patient in the Blegdam Hospital² suffering from pneumonia of the right lower lobe. This organism was not described, however, until 1935 by Kruffmann.³ In 1941, Fournier⁴ again found *S. blegdam* in the blood of a patient in Shanghai, China. Atkinson and associates⁵ recorded in 1944 the occurrence of this bacterium in blood and feces of four cases of enteric like fever in soldiers in New Guinea. During the first year of the United States reoccupation of the Philippines Stevens isolated four strains of *S. blegdam* and noted his findings in 1946. Two of these four isolations were from the blood of American infantry soldiers with symptoms of paratyphoid infections, one was from the feces of a soldier without apparent enteric fever and the other one was from an ulcerative lesion on the ankle of a Filipino patient with no gastrointestinal symptoms. Cobley and Wilson⁶ in 1946 reported a case of *S. blegdam* septicemia and suppurative pericarditis with recovery in an Australian soldier. This *Salmonella* was isolated both from the blood and pericardial fluid and identified by Atkinson and co-workers. Fenner and Jackson⁶ described in 1946 fifty cases of enteric fever due to *S. blegdam* again in Australian soldiers from New Guinea. The diagnosis was established in seventeen cases by the identification of the organism by Atkinson and associates and in the remainder of the cases by clinical epidemiologic and serologic findings. In 1947, Atkinson and associates recorded additional *S. blegdam* isolations from blood and feces of soldiers and natives in New Guinea and Bougainville Island but as well as can be ascertained seventeen of these strains were obtained from the cases reported by Fenner and Jackson. Five strains from mice and one strain from a guinea pig in a laboratory stock suffering from an epidemic also were found by Atkinson and co-workers.

We wish to report at this time the isolation§ in December 1947 of a strain of *S. blegdam* from the feces of a patient in the Southern Baptist Hospital presenting an enteric type of fever and in extensive erythema. During January 1948 an isolation of *S. blegdam* also was made§ from the blood of a patient in the Touro Infirmary with upper respiratory and gastrointestinal symptoms thought at first to be a viral infection. It is of clinical interest that repeated blood counts during the period of hospitalization showed a persistent leucopenia with depression of the granulocytic series.

Received for publication June 9, 1948.

Presented at the meeting of the South Central Branch of the Society of American Bacteriologists, New Orleans, Louisiana, May 1, 1948.

†Department of Pathology, Touro Infirmary.

‡Department of Pathology, Southern Baptist Hospital.

§We are grateful to Dr. Erich Seltsman and Dr. Ivan Sapirstein, National Salmonella Center, New York, N. Y., for the final identification of both strains of *S. blegdam* isolated by us. Acknowledgment is also made to Miss Louise Cargile, Southern Baptist Hospital, and to Miss Madelein Page, Touro Infirmary, for their technical assistance.

We feel that these findings are worthy of reporting since we have been unable to find any reference in the literature to the previous isolations of *S. blegdam* in the United States. In correspondence on December 24, 1947 with Seligman,* we were informed that this species of *Salmonella* had never before been found in this country. Of further interest is that the second case from which this rare species was isolated again in New Orleans simulated clinically the original one described by Kauffmann³ in Copenhagen. These two strains of *S. blegdam* are thought to be the first isolated from anyone in the United States and from individuals who had never left this country.

Biochemical Activities—The isolation of *S. blegdam* from both blood and feces followed the usual procedure in the study of enteric pathogens. In Kligler's agar, the production of acid and gas in butt, alkaline reaction on slant and hydrogen sulfide occurred. It failed to ferment lactose, sucrose, salicin, dulcitol and inositol. Fermentation with gas production occurred in glucose, mannite, maltose, xylose, sorbitol, arabinose and rhamnose. Indole was not formed. Urea was not split. Milk showed no coagulation. Gelatin was not liquefied.

Antigenic Structure—According to Beigey's Manual *S. blegdam* possesses the formula IX, XII g,m,q —. Because this organism possesses the somatic antigen IX, it is classified in the serological Group D. It is a monophasic flagellated bacillus existing only in phase 1. In our laboratories we were able to identify the somatic antigens only. The identification of the flagellar antigens was made by the National Salmonella Center. (See Table I.)

SUMMARY

S. blegdam was isolated for the first time in Louisiana and probably in the United States by Newton from the feces of a patient suffering with enteric type of fever and extensive erythema during the fifth week after onset.

The second isolation of *S. blegdam* in Louisiana was by Holt from the blood of a patient with upper respiratory and gastrointestinal symptoms closely resembling clinically those of the patient from which *S. blegdam* was first isolated by Kauffmann as well as the type of *Salmonella* fever described by Fenner and Jackson in which complications developed. The organism was found during the second week of the infection in a student nurse.

Neither patient had traveled outside the United States. Both patients gave histories of contact with members of the Armed Forces who had previously served in New Guinea and various posts in the South Pacific Theatre during World War II. No epidemiologic facts, however, could be established on the carrier state of these two contacts or on other possible sources of infection.

Serologically, results obtained on routine febrile and in vitro agglutination tests by Holt failed to be of value in the diagnosis of this infection and led to confusion. Attention is called to the close antigenic relationship of *S. blegdam* to *S. typhosa*.

The final identification of this organism was by analysis of the antigenic structure of which it is composed.

Routine vaccination against typhoid-paratyphoid infections as used in this country afforded no protection against *S. blegdam* in one of the patients.

From a review of the available literature we could find recorded the isolation of only thirty-one strains of *S. blegdam* from human sources prior to the additional two strains now being reported by us.

Diagnosis of this *Salmonella* infection is best established by the isolation of *S. blegdam* from blood, stool, urine, or any source involved.

EXPERIMENTAL THERAPY OF GENERALIZED TORULOSIS IN RATS WITH STREPTOMYCIN

ELIART M. BECK, M.D., AND HASCALL H. MUNTZ, M.D.
INDIANAPOLIS, IND.

IT HAS been pointed out previously in an excellent monograph by Cox and Tollhurst¹ that if any treatment favorably influences the course of torulosis it is as yet unknown. However, a localized lesion may heal spontaneously.

Many forms of therapy have been used to little or no avail. The acriflavine dyes^{2, 3} have been administered by several routes including the intrathecal route, with eventually fatal results. Beck and Voyles,^{4, 5} Hamilton and Tyler, Marshall and Teed,⁶ and many others have used the sulfonamides and potassium iodide with few and very uncertain beneficial results. Jones and Klinek in therapeutic experiments in mice demonstrated that sulfadiazine and penicillin were of no value. The subjects of clinical cases reported by Harford and co-workers⁷ and Cox and Tollhurst¹ did not benefit from penicillin. Stoddard and Cutler⁸ and Hoff¹⁰ have amply demonstrated the ineffectiveness of the injection of the killer organisms and the other *Torula* antigens. Mezey and Fowler¹¹ report one case with a short follow up in which some benefit was derived from the use of intravenous 5 per cent alcohol and dextrose solution. Shapiro and Neal¹² used colloidal silver and immune rabbit serum intraspinally without favorable result. X-ray therapy has been tried without benefit.¹³

Since little or no success with any of the afore mentioned therapeutic agents has been achieved a therapeutic test using streptomycin has been carried out in rats.

In vitro titrations of streptomycin against *Torula** showed little antieruptive activity. Apparently there was no inhibition of the same strain used in this experiment. However, Whiffen and co-workers¹⁴ discovered a highly effective antibiotic against *Torula* in the liquors in which streptomycin was prepared. This agent was effective in vitro but was extremely toxic in vivo and therefore could not be used in animal experiments.

Forty seven medium sized albino rats were selected for this trial since it had been shown previously that the rat is easily infected with *Torula* through intraperitoneal inoculation. In addition it does not succumb to the infection too readily. An inoculum was prepared with the same strain in the same fashion described by Beck and Voyles⁵ in 1946. Each rat received 100,000 organisms intraperitoneally.

One week after the inoculation with the standardized *Torula* suspension treatment was begun. The rats were separated into two groups the control group numbering twenty one and the treated group numbering twenty six. Both groups were maintained under identical conditions and were fed the same type food. In no way was a differentiation made except in that one group was treated with 3,000 units of streptomycin in three doses every twenty four hours for twenty one days. The drug was given subcutaneously over the abdomen.

From the Department of Medicine, Indiana University School of Medicine and Medical Center.

Aided by the Eli Lilly Research Fund.

Received for publication May 15, 1948.

By Dr. Edith Haynes of Indiana University Medical Center Laboratories.

No attempt was made to check the levels in the blood. At the end of the three week period, two of the control group and one of the treated group had died. In ten weeks the experiment was terminated, and at this time there were 61.6 per cent (sixteen) of the treated animals alive and 33.3 per cent (seven) of the untreated controls. In addition it should be pointed out that in ten of the animals in the treated group no lesions could be found either grossly or microscopically at post-mortem examination. Lesions were found in all of the control animals (untreated) with the exception of one animal which died an accidental death by drowning soon after the experiment began.

The clinical appearance of the rats which were being treated showed a remarkable difference from those in the control group. The latter group developed lassitude and somnolence and appeared chronically ill, whereas the treated group showed few or no signs of illness.

In summary, forty-seven animals (rats) were inoculated with *Torula histolytica*, twenty-one served as a control group and twenty-six served as a treated group. Treatment consisted of 3,000 units of streptomycin given subcutaneously in normal saline in divided doses daily. Sixty-one per cent of the treated animals and thirty-three per cent of the untreated animals survived. In ten of the treated group no lesions could be found at post-mortem examination. In only one of the untreated did we fail to find the lesions.

CONCLUSION

In this experiment streptomycin seems to have exerted a beneficial effect upon experimental torulosis. It is not known whether its effect is due to the streptomycin or to some additional factor present in its market preparation.

NUTRITION AND EXPERIMENTAL DIABETES

I THE DIABETIC RESPONSE OF WEANING RATS TO INTRAVENOUS DOSES OF ALLOXAN

GEORGE V. MANN M.D. AND FREDRICK I. STARE M.D.
BOSTON, MASS.

THE induction of diabetes in small animals by subcutaneous or intraperitoneal injection of solutions of alloxan monohydrate is an uncertain procedure. The wide variations in response with these routes of administration are in part related to the rapid inactivation of alloxan by body fluids. In the course of work involving the use of large numbers of young diabetic rats we found it necessary to investigate the relationship of the intravenous dose of alloxan to (1) the selective destruction of pancreatic cells which will lead to diabetes without concomitant injury to other visceral organs notably the liver and kidneys (the validity of metabolic studies in animals made diabetic with alloxan is dependent upon this selective anatomical alteration) (2) the incidence of diabetic response among injected animals and (3) the extent and permanency of the defect of carbohydrate metabolism produced.

EXPERIMENTAL

Young albino rats of the Hisaw or Sherman strains were used. We could detect no strain difference in response to alloxan. The animals were maintained on dog food* before injection. All animals ranged between 30 and 50 grams in weight at the time of injection. A 3 per cent solution of alloxan monohydrate† was prepared in sterile distilled water immediately before each injection. It was found that the available preparations of alloxan monohydrate are often variable in appearance and solubility. The preparations used therefore were assayed chemically by the manometric procedure of Archibald¹ and the dosage was adjusted to the amount of alloxan in the sample. The solution was drawn into a 0.5 ml. tuberculin type of syringe equipped with a one half inch No. 26 needle. The animal was placed in a mailing carton with the tail protruding through a hole in the center of a cork stopper used to close the carton. The container was conveniently clamped to a ring stand. Cleaning the tail surface with a soapy cloth followed by a brisk rub with a dry cloth will adequately dilate the four tail veins without heating. A tourniquet is not necessary.

The needle is introduced, bevel up directly over the vein and on the distal one third of the tail. Veins over the proximal third although apparently larger, are injected with difficulty. The vein is closely attached to the skin,

so the needle must be inserted at a small angle with the tail axis. When blood appeared at the syringe nipple, the calculated volume of alloxan solution was injected quickly. When undue resistance or perivascular blanching occurred indicating extravasation, the animal was discarded. With this procedure one can soon learn to inject about twenty-five rats per hour.

The animals were placed in group cages and at intervals were placed in individual metabolism cages for twenty-four hours. In young rats several criteria may be used for determining the presence of diabetes. The data below are based upon twenty-four-hour urine glucose excretion as measured by a photometric modification of the method of Somogyi² and blood sugar determinations by the method of Remecke³ after a preliminary five-hour fast. Failure to gain weight, polydipsia, polyuria, and, after several weeks, cataract formation are also manifestations of diabetes. A fasting blood sugar above 150 mg per cent or twenty-four-hour urine glucose excretion of more than 0.1 Gm was considered an indication of diabetes.

Fig. 1—The forty-eight hour diabetic response of weanling rats to the intravenous injection of alloxan monohydrate.

Fig. 1 represents the typical forty-eight-hour response of several groups of animals to the various doses of alloxan used. The incidence of diabetes thereafter is to some extent determined by the nature of the diet fed. In general the dog food diet was found to give the best survival. When a purified diet containing 18 per cent protein was used, 100 per cent mortality was obtained in ten weeks contrasting with 100 per cent survival in a similar group of animals maintained on the dog food diet. Table I illustrates the effect of certain diet modifications upon the course of the diabetes, with mortality as a criterion of dietary adequacy.

The groups of rats in Table I were composed of animals with comparable severity of diabetes as judged by the criteria listed. They were placed upon the various diets five days after the injection of alloxan. It will be noted that al

TABLE I THE EFFECT OF DIET UPON SURVIVAL IN YOUNG DIABETIC RATS (ALLOXAN)

DIET	NUMBER OF RATS	SURVIVORS				TOTAL MORTALITY (%)
		DAYS				
		14	28	56	10	
Dog food	8	8	8	8	8	0
10% Protein	7	5	3	2	2	72
20% Protein	8	8	7	4	2	75
40% Protein	8	7	6	4	2	75
40% Protein plus 1% NaCl in water	7	6	5	4	2	72
18% Protein purified	20	14	11	6	0	100
Gaines Dog Meal 13H						

though the mortality at seventy days was approximately the same with various levels of protein, the early mortality was higher with the lower protein levels. The survivors at seventy days represent the animals with mild diabetes. In the various diets the protein was increased at the expense of carbohydrate. The inadequacy of the purified diet, as judged by mortality is striking when compared with either the dog food diet or the semipurified diets (containing 10 per cent brewers' yeast as a source of B vitamins). Addition of 1 per cent sodium chloride did not significantly alter the survival.

The influence of diet upon the severity of diabetes and the survival of the diabetic animals will be the subject of a later publication.

DISCUSSION

The immediate mortality (about 7 per cent) in animals receiving intravenously 70 mg of alloxan per kilogram of body weight has been caused by injury of the liver and kidneys of these animals. The susceptibility of animals to this extrapancreatic toxicity of alloxan appears to be as variable as diabetic susceptibility. Doses above 70 mg per kilogram lead to increasing incidence of this complication.

Selection of the optimum dose is thus determined by two parameters. First doses below 40 mg per kilogram give diabetic responses in so few animals that many animals and much time are lost. Second doses above 70 mg per kilogram often lead to injury of organs other than the pancreas thus complicating later metabolic studies.

The 60 mg per kilogram dose level has been found most practical. The 10 to 20 per cent of nonresponding animals can be used as alloxan controls in many experiments. Such controls may in part answer the criticism that alloxan may act as a nonspecific cellular toxin leading to complications other than diabetes. Thus in our work it has been useful to control each experiment with animals not injected with alloxan and with alloxan injected nondiabetic animals. Although we have not studied these latter control animals with glucose tolerance tests, the twenty-four urine glucose excretion is in effect a tolerance test and would be expected to reveal animals with minimal diabetes.

Histologic studies of animals receiving alloxan have revealed no evidence of renal or hepatic damage attributable to the drug in doses of 60 mg per kilogram of body weight or less. Animals receiving higher doses and dying within forty-eight hours frequently have shown such lesions. Of thirty animals receiving 70

mg per kilogram which survived the injection forty eight hours, only one animal later showed cirrhotic changes in the liver with ascites, and this after a period of fourteen months. This was believed to be a late result of mild hepatic injury by alloxan.

Consideration of the severity of diabetes among the responding animals indicates that with increasing doses the number with severe diabetes increases. This would seem to indicate a range of sensitivity among animals extending from the few animals which respond with severe diabetes through the majority which respond moderately to the few who will not respond at all. Experience with repeated injections of those animals that do not respond indicates that they often are resistant even to 80 to 100 mg per kilogram of alloxan.

It should be emphasized that young rats made diabetic with alloxan offer an extremely sensitive experimental tool for study of nutritional relationships in the course of diabetes. Measurements of body weight, water consumption, or urine excretion offer a simple means of assaying the influence of experimental procedures.

SUMMARY

The diabetic response of weanling rats to intravenous doses of alloxan has been studied.

A procedure has been described which will allow production of alloxan diabetes in the majority of injected animals with minimal occurrence of extra pancreatic alloxan injury.

An experimental plan has been suggested which will allow more adequate control of experiments by utilization of nonresponding alloxan-injected animals as additional control animals.

The course of animals made diabetic with alloxan and surviving more than forty-eight hours is determined in part by diet. Survival is greatest in animals fed a diet of dog food and poorest in animals on a highly purified diet. Higher levels of protein and decreased amounts of carbohydrate favored survival on the purified diets.

MYELITIS FOLLOWING THE ADMINISTRATION OF NEOARSPHENAMINE

DAVID BLANKENHORN, M.D. AND HAROLD C. WOLFF, M.D.
NEW YORK, N. Y.

ONE of the hazards involved in the therapeutic use of arsenicals is the danger of central nervous system reactions. These accidents although rare are serious, causing approximately one half the deaths from arsenical therapy.¹ In a survey of 496,253 protocols, one death due to central nervous system reaction occurred for every 5,398 persons treated and every 28,768 injections given. In a group of 158 patients with central nervous system reactions the mortality rate was found to be 76 per cent.

These reactions include encephalitis, encephalomyelitis and myelitis. Encephalitis is by far the most common. It has been widely described and the usual picture of headache, fever, and vomiting followed by convulsions and coma is well known. Encephalomyelitis, a more rare complication is less widely described. The signs of cerebral involvement usually precede and may mask the evidences of cord lesions. About half these patients have been considered to have encephalitis alone until post mortem examination showed unsuspected pathologic changes in the spinal cord. Because myelitis is uncommonly reported and infrequently considered, the following protocol is presented.

A 25 year old woman was given two intravenous injections of neoarsphenamine by the family physician because she suspected she had been exposed to syphilis. A man with whom the patient had been in intimate contact had been discovered recently to have a secondary syphilitic rash. The patient had no signs of syphilis and a serologic test for syphilis was negative. Nevertheless it was decided that he should be treated. Accordingly the patient was given 0.3 Gm. of neoarsphenamine intravenously without untoward reaction. Seven days later he was given 0.45 Gm. intravenously.

Two hours after the second injection the patient had a severe shaking chill followed by a fever of 39.5 C. and moderately severe malaise. She went to bed and for two days had recurrent chills and fever and anorexia. On the first day the physician gave her 600,000 units of procaine penicillin. On the morning of the second day a faint pink nonpruritic rash of small irregular macules appeared on the face, arms and neck. The patient also noted that her throat was lightly sore and that her eyes burned. The evening of the second day following the second injection of neoarsphenamine the rash faded and the chills and fever subsided but the malaise increased. The patient noticed then for the first time that her feet felt numb and that she had difficulty in walking. She was barely able to walk with assistance to the bathroom and void.

In the twelve hours that followed a painless ensation of numbness crept up the patient's legs to the trunk, arms and neck. As this occurred all voluntary motion was lost in the legs which lay limply on the bed. The patient also developed urinary retention. She was mentally clear and had no pain. There was no difficulty in talking, swallowing or breathing and no difficulty with vision. When the sensory defect was at its maximum the patient noted transient impairment of voluntary motion in the arms and hands. The ensation of numbness

From the New York Hospital and the Departments of Medicine (Neurology) and Psychiatry, Cornell University Medical College.

Received for publication June 9, 1948.

receded from the neck, arms, and upper chest as rapidly as it had appeared, hence on the following morning when she was seen by the physician, a sensory level was apparent above the navel. At this time (the third day following the last injection of neocarsphenamine) there was a low grade fever, malaise was gone, and appetite was returning. Complaints were sore throat, loss of sensation in trunk and legs, inability to move the legs, and urinary retention.

The patient remained at home in bed three more days and did not consider herself seriously ill although she had a slight fever of about 38°C and was bothered by her sore throat. The sensory level did not change nor did motor function in the legs improve. The patient could sit without support after being helped to a sitting position. She voided spontaneously, slowly, at long intervals (sixteen to twenty hours), passing large amounts of urine. On the sixth day frequency and urgency developed quite suddenly, with voiding every twenty to thirty minutes. Distressed by this and discouraged by the lack of improvement in the function of her legs she came to the New York Hospital.

On admission the patient appeared moderately ill but was alert, cooperative, and oriented. Temperature was 37.5°C . There were minimal but generalized lymph node enlargement, mild conjunctivitis, and pharyngitis. A single, small, faintly pink, irregular macule was present on the left cheek. The remainder of the general physical examination was not contributory. Examination of motor and sensory functions showed no abnormalities of the head or neck. There was no weakness or wasting in the arms. Rapid, rhythmic, alternating motion was slightly impaired in the right arm, and the biceps, supinator, and pronator reflexes were slightly more active than on the left. Sensory perception was normal in the neck, arms, and trunk above the level of D 8. From D 8 to D 10 there was dyesthesia to pin prick, light touch, and temperature testing. Below D 10 there was anesthesia to these modalities but vibration and position sense were intact above and below this level. There was no sweat level or pain on percussion over the spine. Superficial abdominal reflexes were absent. The patient could sit without support if assisted to the upright position. The legs were symmetric and without wasting, but were completely flaccid. The only voluntary motion possible in the legs was a slight degree of flexion in the right knee. The tendon reflexes were normal but slightly more brisk in the right leg. Plantar responses were extensor. There were mass withdrawal responses in the legs. Rectal sphincter tone was normal but the perianal region was anesthetic. The patient was able to void spontaneously but was forced to urinate every twenty to thirty minutes in order to escape incontinence of urine.

On admission, urinalysis showed only an occasional white cell. Repeated analysis showed no albumin or red cells. The blood urea nitrogen was 11 mg per 100 milliliter. The Mazzoni reaction was negative and remained so. Blood counts were within normal limits. Heterophile agglutinations were negative on admission and ten days thereafter. Culture from the throat showed a mixed flora with no predominating organism. A patch test with neocarsphenamine on the seventh hospital day produced a 2 cm indurated erythematous area in sixty hours. Lumbar puncture on admission gave crystal clear fluid with no evidence of block or increased pressure. Repeated cerebral spinal fluid cultures and Wassermann reaction were negative. Cerebral spinal fluid sugar and chloride determinations were within normal limits. The results of repeated lumbar punctures were as follows:

DAY	LYMPHOCYTES	POLYMORPHONUCLEARS	PROTEIN
1	3	0	55
2	4	1	39
7	6	2	24
13	5	0	30

There was slow but steady improvement which began with a slight regression of the level of anesthesia on the first hospital day. On the second hospital day the patient disclosed that she had received two injections of neocarsphenamine. Because of previous report of myelitis following neocarsphenamine injections, it was decided to begin British anti-lewisite (BAL) therapy. A total of 1,300 mg of BAL was given over a four day period. By the eighteenth hospital day anesthesia was confined to a few spotty areas on the lower legs and in the perianal region. These changes persisted and in the entire area which was

formerly anesthetic there was dysesthesia to pin, light touch and temperature testing similar to that found in the area from D 8 to D 10 on admission. The patient gradually regained voluntary motion and strength in the legs but improvement was retarded by the transient appearance of a moderate degree of extensor spasm. The reflex abnormalities in the arms and legs did not change with the exception of the plantar reflex which became flexor. The patient was able to walk without support on the thirty seventh hospital day. She continued to have frequency of urination but the interval had increased to one to two hours.

Most standard texts do not list arsenical myelitis as one of the toxic manifestations of arsphenamine therapy. So few cases have been reported that it is impossible to draw inferences as to cause and effect as has been done with arsenicals and encephalitis. In all, there are only nine cases similar to that of the patient herein described.³ The chance occurrence of myelitis of unknown cause in a patient receiving arsenicals must be considered. The case reports are so few that no clear cut clinical picture is typical. However many of the reports are strikingly similar. Scott and Remhart⁴ describe a patient in whom the onset and progression of symptoms were almost identical and followed the second injection of neoarsphenamine. This patient however did not survive. Many patients have been suspected of having had Herxheimer reactions and only one previous patient did not have syphilis. However in the few that have been autopsied the histopathology of the cord was similar to that in the brains of patients with encephalitis and in the cords and brains of those with encephalomyelitis.

In the New York Hospital case the possibility of a Herxheimer reaction may be waived. The possibility of intercurrent myelitis of other cause remains and cannot be eliminated.

BAL has been shown by Stocken and co workers to protect rats from lethal doses of therapeutic arsenical compounds.⁵ Eagle and Magnuson⁶ have reported fifty five cases of arsenical encephalitis treated with BAL. The overall mortality rate was 11 per cent as opposed to 76 per cent of an earlier untreated series. Severe cases with convulsions, coma or both were observed to respond dramatically in twenty four to seventy two hours particularly if BAL was given early. There is now a convincing body of evidence that the toxic effects of arsenicals are due primarily to the fact that they combine with and block physiologic enzyme systems vital to the cellular economy. The antidotal action of BAL is referable to its ability to remove arsenicals from combination with these enzyme systems in the cells. There has been discussion as to whether the central nervous system reactions from arsenicals particularly myelitis are due to toxicity or sensitivity. The fact that BAL has been dramatically effective in encephalitis suggests that the mechanism here involves toxicity, reversible with early BAL therapy. Since the histopathology is similar in encephalitis and myelitis, it can be postulated that myelitis is a toxic reaction which should respond just as dramatically.

In the New York Hospital case BAL was given too late to allow inferences concerning therapeutic or diagnostic values. Yet the outcome here is unusual since only two of the previously reported patients survived one with severe residuals. If myelitis following the injection of neoarsphenamine is due to toxic effects of this agent it should respond to BAL when given early. It would be one variety of myelitis for which there is a specific therapeutic agent.

SUMMARY

Myelitis following the administration of neoarsphenamine is a rare but serious complication of arsenical therapy. It is suggested that, if arsenical compounds have been given to a patient developing myelitis, BAL therapy be instituted.

LABORATORY METHODS

RECOVERY AND ESTIMATION OF RADIOACTIVE ISOTOPES FROM BIOLOGIC TISSUES

I GOLD

RAYBURN W DUNN, BS MS*
BERKELEY, CALIF

IN ORDER to study the distribution of gold in animal and human tissues it was necessary to develop a rapid and quantitative method for the recovery and estimation of this element. Toward this end use was made of the experience gained, during 1942 and later, with the electrodeposition methods employed on the Manhattan Project (unpublished papers^{1, 2}). Investigations along these lines also were encouraged by the successful use of electrodeposition in the determination of radioactive iron by Ross and Chapin³, Hahn⁴ and others.

By the use of the electrodeposition technique thin uniform films of the radioelement may be obtained which then can be used for the determination of radioactivity. Standard Geiger or alpha counters are employed for these measurements as the case may be.

As early as 1918, DeWitt, Caldwell, and Leavell had shown that it was possible to determine gravimetrically the amounts of gold present in biologic tissues after electrodeposition on platinum electrodes. Details of the method employed by these authors could not be found although a brief description was furnished, namely, Kjeldahl digestion, followed by evaporation to about 1 cc, treatment with aqua regia and ammonia, and neutralization with HCl. The solution was filtered, made slightly acid with HCl and buffered with phosphoric acid sodium phosphate. Electrodeposition was carried out in 40 cc of solution at 60°C and 1 to 12 volts. Current density was not given. Recoveries of 80 to 100 per cent were obtained with 0.02 to 0.3 mg of gold.

Scott^{5, 6} gives methods for the determination of gold in electroplate baths and also outlines a microanalytical procedure⁷ all using platinum anodes and cathodes and potassium cyanide plating solutions. Procedures for the commercial plating of gold are given in standard references and trade journals^{8, 9}. Most of these methods employ gold anodes and either chloride or cyanide plating baths.

In general, the method herein described follows closely the standard procedures for the separation and electrodeposition of gold.

EXPERIMENTAL

Electrodeposition Apparatus—The anode consists of 0.040 inch diameter platinum wire wound in a flat spiral. The vertical length of wire is sealed into glass and both are connected into a suitably drilled brass rod $\frac{3}{8}$ inch in diameter. The latter is fixed in the chuck of a stuffer rotating at about 300 revolutions per minute.

Cathodes are $1\frac{1}{2}$ inch diameter disks, 0.002 inch thick, either of platinum or gold-plated copper. Platinum must be used for exacting work, but for reasons of economy the plated copper was substituted in carrying out these experiments.

Fig. 1—Electrodeposition cell

The electrodeposition cell^{*} shown in Fig. 1 uses a $1\frac{1}{2}$ inch outside diameter Pyrex tube, 3 inches long.

Operating current is supplied from two cells of a 6-volt storage battery. An ammeter with a range of 0 to 1 ampere and a 1-watt, 20 ohm rheostat are placed in series with the electrodeposition cell. The actual apparatus† consists of twenty-four such units arranged in two banks of twelve each. Each unit has a toggle switch for throwing the ammeter in or out of the circuit. For work with gold, a better arrangement would be to use an ammeter with a scale of 0 to 0.2 amp and a variable resistance of 50 ohms. Each unit should have a fuse to protect both the ammeter* and the resistance, and a voltmeter should be provided to measure the potential drop between anode and cathode. The apparatus used for this work had been built for another purpose and could not be modified in the time available.

Procedure—The weighed tissues are digested in 25 ml Erlenmeyer flasks, using either aqua regia or concentrated nitric acid plus superoxol. In either

*Detailed drawings can be furnished upon request.

†Designed and constructed by Mr. Robert Loevinger of this laboratory.

case, only small amounts of reagent are added at one time. If excessive frothing is encountered 1 drop of octyl alcohol is added. Complete oxidation of the latter, as well as the tissue, must be accomplished before proceeding further.

As a carrier, 2.0 ml of a reagent grade gold chloride solution may be added either before, during or after digestion, although addition at an early stage in the digestion is recommended. The concentration of this solution should be accurately known, and the solution should contain approximately 5 mg per milliliter of metallic gold as the chloride. The concentration of gold in the carrier solution is determined either by electrodeposition on tared platinum disks or by evaporating a known volume to dryness in a tared porcelain crucible followed by heating to decompose the chloride, cooling and weighing.

Upon completion of digestion, excess nitric acid is removed by adding successive small amounts of concentrated HCl with heating. The resulting solution is evaporated to 1 to 2 ml and transferred to a 15 ml centrifuge cone. Only a roughly quantitative transfer is needed since the electrodeposited film is to be weighed, and recoveries as low as 90 per cent or even 80 per cent are acceptable.

The separation of the gold from all or nearly all of the associated elements in the tissue digest is accomplished by reducing the gold to the metallic state. The reducing solution is made up to contain approximately 10 per cent $\text{NH}_2\text{OH}\cdot\text{HCl}$ and 0.4 per cent $\text{FeSO}_4\cdot 7\text{H}_2\text{O}$. Two milliliters of a freshly prepared solution are used for each 10 mg or less of metallic gold. Reduction is hastened by placing the cones in a beaker of hot water which is kept just below the boiling point for fifteen to thirty minutes. The ferrous sulfate is omitted from the reducing solution when urine and feces samples are to be run.

After centrifugation, the supernatant liquid is discarded. The centrifuge cone wall and the gold may be washed and centrifuged and the wash solution also discarded. Although this is not considered necessary for routine work, it was carried through when the set of determinations shown in Table I was made.

The pellet of precipitated gold is readily dissolved in a mixture of 4 drops of hydrochloric acid plus 1 drop of nitric acid. Placing the cone in a beaker of hot water accelerates the reaction which is usually complete within fifteen minutes.

The aqua regia solution of gold is made all at once with 5 ml of 1N sodium hydroxide. After mixing, this solution is transferred to the electrodeposition cell. The latter should be assembled with a tared and numbered disk and should have 2 ml of a 5 per cent solution of potassium cyanide in 0.1N sodium hydroxide covering the disk before the gold solution is added. The centrifuge cone is washed with distilled water, which is also poured into the cell. In routine work this is accomplished by filling the cone once with distilled water, followed by transfer to the cell.

The anode is placed in the solution at about $\frac{3}{4}$ to 1 inch from the cathode. The current is adjusted to approximately 85 milliamperes. Since the actual plating area is about 8.5 sq cm, the current density will be 10 Ma per square centimeter, or approximately twice the current recommended for commercial electroplating.*

Deposition is allowed to proceed for one hour at room temperature. At the end of this time an additional 2 ml of the cyanide solution are added, followed by another hour of electrodeposition.

Upon removal of the anode the cell contents are discarded, and the cell is washed with distilled water. After disassembly the disk is again washed, rinsed in acetone, and placed in a warm place to dry. The gross weight is generally obtained before the radioactivity is determined, although this is not essential.

Notes on the Analytic Procedure —

Digestion As often happens in the wet digestion of biologic tissues, there are occasional samples which precipitate sparingly soluble crystalline salts upon evaporation to small volume. When such occurred during this work, the solution and precipitate were transferred together to the centrifuge cone and the procedure was carried through as with the other samples. The presence of this material, which was always in very small amounts, apparently did not interfere with the results. To insure that no radioactive gold is lost, however, any insoluble material should be dissolved at some point between the time the carrier is added and the time reduction is completed, even though an extraneous precipitate appears later as it frequently does with urine and feces samples. This precipitate does not interfere with the electrodeposition. When octyl alcohol is used to prevent frothing, a waxy material is frequently formed which has a low melting point and which may not be observed until the solution is cooled to below room temperature. Precautions should be taken to obtain complete digestion of this organic matter.

Reduction The use of both hydroxylamine and ferrous sulfate was investigated. The latter reduced the gold more rapidly than the former, and there was usually a small amount of unvettted gold floating on the meniscus after centrifuging. This gold was either lost upon decantation or had to be removed on a stirring rod and returned later. Reduction with hydroxylamine occurred in three distinct phases, namely, reduction to aurous, formation of colloidal gold, and finally, precipitation of the metal. Unvettted gold was not usually obtained when this reagent was employed, but the formation of a light gold mirror was observed frequently. When a mixture of both reductants was used, both phenomena were less pronounced, and the rate of reduction was about the same as with ferrous sulfate alone. The influence of acidity and salt concentration upon the rate of reduction and the character of precipitated gold was not investigated. A considerable range of conditions was encountered, but the results in all cases were satisfactory.

Solution of Gold in Aqua Regia When mirror formation was encountered, the cone was placed in only about 1 inch of hot water to hasten the dissolving reaction. Sufficient aqua regia condensed on the wall of the cone to dissolve the mirror completely.

Addition of NaOH If insoluble salts are present after digestion, a white precipitate is sometimes present or is formed at this point. If desired, this insoluble material may be removed by centrifuging before the solution is transferred to the electrodeposition cell. This was not done with the experiments reported.

The Cathode Disk Both platinum and gold plated copper disks may be cleaned by immersion in warm concentrated sulfuric acid dichromate cleaning solution. With the latter type of disk, immersion should not be for longer than two to three minutes, since the plate does not offer sufficient protection to the copper to prevent its dissolving. Both types of disk must be thoroughly rinsed with water after this treatment. The platinum disks may be dried directly after washing but an acetone rinse is recommended first for the gold plated copper. Heating the platinum disks over a burner in order to dry them is not recommended, since they then lose their temper and are more difficult to handle without bending. Early experiments carried out by Bertrand¹⁰ indicated that plain copper disks lost rather than gained weight during electrodeposition. Without investigating this problem further, it was decided to try gold plated copper disks in the hope that the formation of oxide film on the surface of the copper and attack of the copper by the cyanide plating solution could thus

be reduced or eliminated. The alternative was to use either gold or platinum disks, which in view of the number needed and the difficulties involved in removing the radioactive layer would not be economical. While the use of plated copper did not entirely eliminate the weighing error, the results obtained were satisfactory for this type of analysis. The thickness of the commercially made gold plate was not determined. The actual plating was done on strips of copper 14 by $1\frac{1}{4}$ by 0.002 inch. The $1\frac{1}{4}$ inch disks were then punched out.

Electrodeposition. It was frequently observed that the plated disks in the assembled cells would discolor upon transference of the gold solutions to them. This occurrence was minimized but not entirely eliminated, by adding the cyanide solution to either the cone or the electrodeposition cell before transference. The addition of the KCN directly to the cone prevents precipitation of auric hydroxide; the latter sometimes occurs upon allowing the solution to stand for several hours with NaOH alone. Neither the cause of the discoloration reaction nor its influence upon the gravimetric determination was investigated. The color of the gold plate on platinum disks was either yellow or light orange while that on gold plated copper varied from light rose to brown. The color in the latter case is pointed out by Weisburg and Graham* may be due to the presence of copper (from the cathode) in the plating solution. Gold plates on platinum frequently showed small blisters in which case the deposit was easily broken loose by scratching. The use of a wetting agent such as one of the alkyl aryl sulfonates as suggested by Hartshorn¹¹ might eliminate this difficulty. Blistering was not observed with the plated copper disks but the deposit on these disks could be rubbed off to an appreciable extent perhaps because of the admixture of copper, hence highly active disks must be handled carefully in order to prevent contamination of counters, and so on, due to powdering off of small unweighable amounts of gold. The decision to use alkaline cyanide plating solutions rather than acid chloride was based upon the assumption that in the case of the latter there probably would be some attack of the platinum anode due to the formation of free chlorine and therefore deposition of platinum with the gold. The possibility of attack on the platinum by the cyanide however is not ruled out.

ANALYTIC RESULTS

The data shown in Table I should be divided into three groups. Determinations 77 through 84 were carried out with what is considered to be the proper amount of carrier gold to insure complete recovery of the radioactivity and at the same time to give a sufficient amount of deposit for gravimetric purpose, namely 10 milligrams. Determinations 85 through 92 were carried out with less than 10 mg of carrier gold. With both of these groups, the various solutions were added directly to the assembled electrodeposition cells as follows: 5 ml of 1N sodium hydroxide, 4 drops of hydrochloric acid, 1 drop of nitric acid, 2 ml of 5 per cent potassium cyanide, the carrier gold solution and the radioactive gold solution. Distilled water was added in each case to make a total volume of approximately 30 milliliters. Determinations 77 through 92 were actually eight sets of duplicates.

The third group comprises Determinations 93 through 96. This group of four identical determinations was carried out to test the recovery and electroplating procedures under carefully controlled conditions. For this purpose three normal adult mice weighing 20 to 25 grams each were dry ashed in the muffle furnace at 600° C. The ash was taken up in aqua regia and the excess nitric acid removed as outlined under Procedure. The resulting solution was diluted to 150 ml and 10 ml portions were used for each of these four determinations. The carrier and radioactive gold solutions were added and the foregoing procedure was then followed.

†Weight not obtained

Two typical sets of biologic data are given in Table II. These data were collected during the course of the work with arthritis carried out by Bertrand and co workers¹²

DISCUSSION

No explanation is offered for the 101 per cent average recovery of added gold, Table I. Since the error involved in biologic work is usually greater than the error which would be introduced by using the per cent carrier gold recovery as a factor in calculating the radiogold recovery, no further work was carried out to eliminate this discrepancy. The per cent recovery values shown in Table II therefore were used in calculating the original tissue gold activity¹ not reported herein.

One surprising result obtained as shown in Table I (Determinations 85 and 86), was the 91 per cent recovery of radioactive gold when no carrier gold was added to the solution in the electrodeposition cell. The solution of radioactive gold contained 5 μ g of metallic gold per milliliter in the form of sodium gold thiosulfate. The quantitative recovery of gold during electrodeposition therefore was greater than one would be led to expect the losses in disk weight notwithstanding.

In carrying out the gold purification procedure with tissue digests from the arthritic patient ferrous sulfate was used as a reductant. Trouble was experienced only with the urine and feces samples. Upon adding the reductant to the digested solutions from these samples a red brown flocculent precipitate was obtained in three of four cases. The fourth case appeared to give a normal precipitate, but unfortunately the sample was lost upon centrifuging and a better observation could not be made. The abnormal precipitates were completely soluble in concentrated HCl showing that reduction had not occurred. The addition of hydroxylamine to these samples gave normal precipitation of the gold. The use of the mixed reducing solution with these two types of sample is not recommended, hydroxylamine alone should be used.

The results with the rabbit tissue samples also shown in Table II were obtained using hydroxylamine alone as a reductant. All determinations given in Table II were carried out using routine or roughly quantitative transfer techniques.

SUMMARY

A method is described for the recovery and estimation of radioactive gold from biologic tissues.

The results obtained with this procedure are well within the allowable error for this type of determination.

Under a rather wide range of conditions satisfactory results were obtained in all cases.

The method is rapid requiring no special techniques and the electrodeposition equipment is fairly simple.

The author is indebted to Dr J H Lawrence, Dr C A Tobias and Dr J J Bertrand for assistance and advice and to Jean Luce for the digestion of the many biologic samples needed for this work.

The radioactive gold samples at first were supplied through the courtesy of J G Hamilton and later by the Atomic Energy Commission

THE USE OF PRESERVED ERYTHROCYTES FOR THE DETECTION AND IDENTIFICATION OF Rh ANTIBODIES

PAUL G. HATERSLEY, M.D.,* AND MARGARETTE L. FAWCETT, B.S.†
SAN FRANCISCO, CALIF.

AN IMPORTANT requisite for any Rh testing laboratory is a constant supply of group O human erythrocytes of various Rh types. For the qualitative detection of Rh antibodies, cells of types CDE (Rh₁Rh₁) and cde (Rh negative) are highly desirable while for accurate identification of the antibodies which are encountered, cells of Cde (Rh') cDe (Rh₁) and cdf' (Rh') and occasionally other rare types must be available. Even the largest blood typing centers frequently have difficulty obtaining donors of the desired types however and to the smaller laboratory this difficulty may constitute an insurmountable handicap to adequate antibody testing.

We have attempted to solve this problem by preserving blood specimens in anticoagulant solutions. We have found as has been reported by others that when blood is mixed with an appropriate volume of sterile Alsever's or a cde solution and is stored in the refrigerator it keeps with a minimum of hemolysis for many weeks. In evaluating such preserved blood for our purposes there were two questions which demanded an answer: (1) Do the cells retain their agglutinability? (2) Do they retain their specificity? In a preliminary attempt to answer these questions the following study was made:

A donor group A MN Rh₁Rh₁ (cDE/cde) was bled aseptically and 5 cc of the blood were mixed in each of a series of capped bottles with 5 cc of sterile Alsever's solution. One bottle was withheld for immediate study and the remainder were stored at refrigerator temperature (4°C). At weekly intervals one bottle was removed from the refrigerator for study and discarded.

Each specimen was titrated against a standard anti-D (Rh₁) blocking serum of proved keeping qualities in the following manner:

- (1) An approximately 2 to 3 per cent suspension of cells was made in 30 per cent bovine albumin† by adding 2 or 3 drops of the blood anticoagulant mixture to 1 cc of albumin.
- (2) The standard anti-D (Rh₁) serum was serially diluted in normal AB serum and 1 drop of each dilution was placed in a series of small agglutination tubes.
- (3) To each tube was added 1 drop of the cell suspension.
- (4) All tubes were incubated in a 37°C water bath centrifuged three minutes at moderate speed and examined under the dissecting microscope for agglutination which was recorded as 1 plus to four plus.

The titers obtained are recorded in Table I. It may be seen that there was only very little fluctuation in titer, probably due entirely to variations in technique until the seventh week. At that time there began a definite decrease in titer which was proved by adequate controls not to be due to deterioration of the serum. It was at this time that the stored blood first showed gross hemolysis.

Received for publication June 1948.

*Grossly hemolyzed

†Fresh cells of same donor tested against stored serum at same time as 9 week old cells

A saline cell suspension of each specimen was likewise tested against the high-titered human anti-A and anti-B sera which are routinely used in this laboratory for Landsteiner grouping as well as against the routine Rh subtyping sera. In every case the reactions were exactly as they were when the blood was fresh. No false agglutination or false negative reactions occurred.

Similar observations have been made since in blood specimens of all of the Landsteiner types and a wide variety of Rh and H₁ types. In the two years that Alsever's and a c d solutions have been used in our laboratories, there has never been any evidence that cells preserved in this way are not perfectly reliable for Rh testing as long as there is no gross hemolysis. This period has varied in our hands between two and eight weeks, depending upon the care with which contamination is avoided and the amount of agitation to which the cells are subjected.

DISCUSSION

The advantage of a satisfactory preserving medium for blood cells for Rh testing is perfectly obvious. Since the introduction of the Alsever technique into our laboratories we have had little difficulty in keeping ourselves stocked with cells of all of the Rh subtypes which we have needed in our work. It is simple to keep a roster of patients and donors of various types, and at periods of a few weeks or a month to call in the appropriate individuals for renewal of the store of preserved bloods. We have found it most satisfactory to divide each donation between two or more bottles of anticoagulant, so that if one becomes contaminated or hemolyzed in handling, the supply of cells will not be lost entirely. When cells of some particular type are needed for testing, a few drops are drawn aseptically from the appropriate bottle and a cell suspension is made up in saline or albumin. If one is using a technique such as the slide test of Diamond and Abelson or the conglutination test of Wiener in which the presence of an aqueous solution of sodium citrate might interfere with the test, it is necessary to centrifuge the mixture, pour off the supernatant, and resuspend the cells in undiluted serum or plasma.

We feel that this method of preserving blood has become an indispensable adjunct to the proper functioning of our blood grouping laboratory

SUMMARY

Alsever's and a c d solutions have been found valuable for preserving whole blood of various antigenic types. Cell suspensions made from such preserved blood are satisfactory for testing sera for the corresponding Rh and Hr antibodies.

METHODS TO INCREASE ACCURACY IN THE USE OF HAYEM'S SOLUTION FOR RED BLOOD COUNTS

EDNA H. TOMPKINS, M.D.
NEW HAVEN, CONN.

IN 1934 Bryan and Garrey¹ published a description of a rotor for the mechanical mixing of blood in diluting pipettes which affords more exact white counts than other methods of mixing. The erythrocytes, however, often were found to ball when diluted with the usual diluent for red blood counts, Hayem's solution. This effect was found to be due to the bichloride in the diluent, and Toison's fluid was therefore recommended for red counts.

Ch'u and Forkner² observed clumping of erythrocytes with the use of Hayem's solution in certain pathologic conditions even when the pipettes were shaken by hand, and they suggested substitution of Gower's solution to avoid the presence of bichloride.

Neither of these suggestions, as is also true of other substitutions that have been offered over the years, has received popular adoption. The reasons for this are several: either the diluents suggested were impractical for the general run of cases and laboratories, or the precautions offered in the use of them, as well as of Hayem's solution, proved inadequate upon wider usage, or custom on the part of the medical profession at large and the relative degree of satisfaction that has been afforded by the use of Hayem's solution determined that that should remain the diluent of choice for red counts.

Hayem³ devised the formula which is now in common use as a diluent for red counts at a time when blood counts were beginning. His methods of obtaining and mixing blood, and even of superimposing it on the chamber for counting, were less refined than those employed today, and the demands for accuracy were correspondingly different. Nonetheless, use of the fluid has sufficiently stood the test of time to be continued regardless of the dissenting voices from period to period. As Ch'u and Forkner² have enumerated, the ideal diluent should preserve the cells and sharpen their visibility without danger of destroying any of them or of too greatly distorting them, should keep without deterioration, should eliminate danger of growth of organisms, and should permit satisfactory distribution of cells in the pipette and on the counting chamber. Hayem's solution fulfills all the criteria outlined for an ideal diluent except the indispensable one of dependably satisfactory distribution of cells. With mixing by hand, or with vigorous mechanical shaking, errors due to unsatisfactory distribution can usually be reduced, though not eliminated. With the advent of the mechanical rotor which was proved so satisfactory for white blood counts, which can rotate as many as eight pipettes simultaneously, and is therefore desirable as a time-saving device for clinical and research laboratories

and which is now manufactured commercially the inequalities of distribution of erythrocytes in Hayem's solution have become more evident and more in need of remedy

In view of the fact that the suggestions already made for substitution of other diluents for red counts have failed to be adopted it seemed preferable to attempt modification of Hayem's solution in such a manner as to eliminate the dangers to distribution inherent in it, rather than to encourage further use of different diluents. Such modification has been attained in one of two ways either by reduction of the proportion of bichloride to as low as that recommended by Jorgensen,⁴ together with careful control of the pH of the diluent between 5.0 and 7.0, or by addition of such colloids as gelatin or lecithin to Hayem's or Jorgensen's solution without concern for pH below 7.0. Chu and Forkner found Jorgensen's solution unsatisfactory in the cases that they studied, but as the importance of the hydrogen ion concentration in the use of Jorgensen's solution was not recognized at that time it is probable that failure to control that factor featured in their findings.

The gentleness of the movements of the rotor of Bryan and Garrey served as a tool to show that the danger of clumping with Hayem's solution often is masked by other methods of mixing, but is actually inherent in the use of bichloride in diluents irrespective of the manner of mixing. The rotor permitted analysis of the causes that underlie the clumping and that feature in the remedies which assure against it. These studies are given in detail in a companion paper. This report will be confined to the practical points in the preparation and use of the modifications of Hayem's solution that have been found to prevent clumping, and to comparison between red blood counts made with Hayem's solution and with the modified diluents.

METHODS

The formula for Jorgensen's solution is as follows

Na ₂ SO ₄	2.5 Gm
NaCl	0.5 Gm
HgCl ₂	0.05 Gm
H ₂ O (distilled)	100 cc

The formula for Hayem's solution modified by the addition of gelatin is as follows

Na ₂ SO ₄	2.5 Gm
NaCl	0.5 Gm
HgCl ₂	0.25 Gm
Gelatin	0.01 Gm
H ₂ O (distilled)	100 cc

The gelatin used was a powdered preparation. Other preparations were not tried but it is judged that any preparation of sufficient purity to rule out the presence of harmful electrolytes would be satisfactory. It should of course, be kept dry for weighing.

Preparation of Hayem's solution containing gelatin is made most easily by dissolving (1) the desired amounts of sodium sulfate sodium chloride and gelatin in one half the de-

⁴Sollas Bacto Gelatin by Difco Laboratories Detroit Mich

sired amount of water, warming if necessary to hasten solution of the gelatin, and (2) the desired amount of bichloride in the other half of the desired amount of water. When the two solutions are complete they should be mixed, with precautions to avoid foaming, and stored. Where large amounts of the diluent are desirable because of frequency of demand, it is helpful to make a sufficient supply of the double strength bichloride solution and to mix this with fresh batches of the double strength saline gelatin mixture as desired. The double strength bichloride solution keeps indefinitely in Pyrex glass and may be filtered, if necessary, before mixture with the solution containing gelatin. The mixed solution must not be filtered, but merely decanted, should the precipitate occur that is common in saline solutions of bichloride.

Both of the modified diluents should be kept in Pyrex containers since solution of the glass inevitably carries the danger of elevation of the pH to the point where clumping of the red cells cannot be prevented. Furthermore, even readjustment of the pH—if it has become elevated by solution from a container—is not sufficient to avoid clumping. This indicates, of course, that electrolytes dissolved from glass must have effects upon clumping in addition to those produced by increase in the pH*. It has been determined that either of the modified diluents can remain in contact with the particular types of diluting pipettes that were used for these experiments for as long as twenty four hours without change in pH.

Red counts made with the modified diluents were compared with counts made with the standard Hayem's solution. The counts were carried out under experimental conditions that were planned to simulate conditions that might occur in routine clinical use. Judgment as to satisfactory distribution for blood counts was made, first and foremost, by microscopic inspection of the filled counting chambers. The counts were carried out merely for experimental assurance that they would, in reality, meet the usual standards for red blood counts. They were not planned primarily for a comparison on a statistical basis, and although the number of counts with any given diluent is considerable, the number for any given condition with that diluent is admittedly too few for satisfactory statistical analysis. When compared on that basis, nevertheless, the groups of counts with each of the diluents do show trends that are in agreement with the conclusions based on the microscopic studies. Therefore the significant data from the counts are presented in Table I and Fig 1, and are discussed as probable statistical support of conclusions that depend primarily upon microscopic studies. As additional security a larger series of counts made with Hayem's solution alone and with Hayem's solution containing gelatin was obtained for a single experimental condition. This material is presented in the discussion of the experimental data.

The blood for all of the pipettes for any given series of counts was drawn at the same time from a freely flowing finger stick. The same subject and observer were used throughout. Both Haak and Trenner automatic pipettes were used in the comparison. No differences due to the model of pipette were found. The pipettes always were given ten quick shakes by hand immediately after filling. The mixing of the blood with diluent was carried out by different methods which were, in turn, employed for different periods of time. When the blood was mixed by rotation, a commercial model of the Bryan Garrey rotor was used. It was tested against one of the original experimental models and was found to give identical results. When the blood was mixed by a mechanical shaker, an experimental model devised by Beard† was employed. In some instances mixing was started at once. In others, the pipettes were allowed to stand for various intervals before mixing was started. These data for the different sets of counts are given in Table I. Levy-Hauser counting chambers with the improved Neubauer ruling were used throughout. Twenty or more drops always were expelled from the pipettes before the chambers were filled. When successive drops were to be counted from a single pipette, ten or more drops also were

*I wish to thank Dr. Ann Minot, Department of Biochemistry, Vanderbilt Medical School, Nashville, Tenn., for these determinations and for the helpful interest which initiated investigation of the causes which underlie the clumping of blood with Hayem's solution.

†The model was made while Dr. Beard was connected with Vanderbilt Medical School, Nashville, Tenn. Similar models have been used in numerous laboratories through the courtesy of that school.

expelled between each filling and all chambers were filled in sequence. Those not to be counted at once were allowed to stand on moist paper under a bell jar.

There was a striking tendency for the red cells to become aligned with the lines of the chamber and to leave the centers of the small squares relatively depleted of cells when the diluent contained gelatin and the chamber was allowed to stand for any considerable time after filling. Since analysis of the data to follow indicates a gain in accuracy in

Fig 1—Scatter chart showing the number of counts in a series that fall within any given deviation of the mean of the series. Experimental conditions can be obtained by reference to Table I

counts made in the presence of gelatin, this alignment of the red cells would seem to be unimportant to the accuracy of the counts and to represent simply a mutual shift in position of cells that had been well distributed, rather than a basic fault in distribution.

In conformity with the usual clinical routine five small squares of the counting chamber that is, one fifth of a square millimeter, were included for each count. The values are

sired amount of water, warming if necessary to hasten solution of the gelatin, and (2) the desired amount of bichloride in the other half of the desired amount of water. cells was observed in Jørgensen's solution with normal blood when the values for pH were below 5.0. With values above that lysis was not detected in normal blood nor in a patient with congenital hemolytic icterus in relapse*. The saline fragility of this patient at the time of the observations was above 0.56, the red count, 2,560,000, the reticulocyte count, 12.8 per cent, and the icteric index, 15 units. The erythrocyte counts of this patient made from pipettes diluted with Jørgensen's solution and allowed to stand for as long as twenty-four hours before counting did not differ from those from similarly filled pipettes that were counted immediately nor from pipettes that were diluted with Hayem's solution containing gelatin. Lysis must be detected by observation of fading cells or through comparison of counts made by methods in which there is no question of lysis, since the effect of bichloride upon any liberated hemoglobin conceals the reddening of the suspension which ordinarily announces hemolysis.

Berkson and co-workers* do not state specifically what diluent they employed in their series of statistical studies concerning the limits of significance in red blood counts, but they do state that they used the methods in common practice. It is therefore assumed that they used Hayem's solution. Since the clumping that has been found to be an underlying tendency in the use of this diluent may often be so slight as to escape attention it is reasonable to suppose that the values which these authors obtained are greater than would be the case had they used one of the modifications of Hayem's solution discussed in the present studies. This assumption is strengthened by the counts made in these studies. It will be seen from the table that when Hayem's solution alone was used, the standard deviations were at times as great as those found by Berkson and co-workers, namely 37.5 counted erythrocytes (375,000 total red blood cells). In the counts with Hayem's solution containing gelatin or with Jørgensen's solution under controlled conditions the values are decidedly lower.

CONCLUSIONS

Hayem's solution carries an inherent capacity for the halting or clumping of cells when used for red blood counts. The tendency toward clumping is magnified by gentle rotation but underlies all manners of mixing. It affects the dependability and accuracy of counts made with Hayem's solution.

The capacity for clumping inherent in Hayem's solution is due to the component of bichloride. It can be eliminated by decrease of the proportion of bichloride to that of Jørgensen's solution, together with control of the pH of the diluent between 5.0 and 7.0 or by addition of gelatin to Hayem's solution without concern for pH below 7.0.

Counts made with these modifications of Hayem's solution are subject to less deviation than are counts made with Hayem's solution alone under the same conditions.

*Case History No. 11,383 Vanderbilt Hospital Nashville Tenn. I am very grateful to Dr. Edgar Jones and Dr. Henry Warden, Department of Medicine, Vanderbilt Medical School Nashville Tenn., for the clinical data concerning this patient and for allowing me to make these studies. I am also very grateful to the Department of Social Service of the Vanderbilt Hospital for the interest which they exercised in helping me to contact this patient.

Use of Hayem's solution containing gelatin allows greater flexibility of experimental conditions without loss of protective power than does use of Jorgensen's solution. Addition of gelatin to Hayem's solution is, therefore, the modification preferred.

A SPECTROPHOTOMETRIC METHOD FOR DETERMINATION OF URINARY BILIRUBIN

GEORGE E. THOMAS, M.D., and DORIS M. KITZBERGER, B.S.
St. Louis, Mo.

A REVIEW of the literature on bile pigment metabolism and tests of hepatic function reveals that many quantitative tests for urinary bilirubin have been proposed. Probably the most satisfactory to date is that devised by Goodson and Sheard¹ in 1940 employing diazobenzenesulfonic acid. In 1941 Scott employed the diazo reagent of Ehrlich and the unit system of van den Bergh in the quantitative determination of urinary bilirubin. His method is the most accurate, being sensitive to 0.02 mg of bilirubin per 100 ml of urine. It is, however, a procedure too difficult and time consuming to be employed as a routine clinical laboratory test. Gelbois and Stokes² employed a modification of the methylene blue test of Frauke³ in their studies of infectious hepatitis in 1945. This was at best only a roughly quantitative test. Stokes and co-workers⁴ in 1946 attempted to adapt the methylene blue test to the spectrophotometer but with little success, principally because the color produced in the methylene blue test is not the color of a true solution but a combination of colors. The barium strip modification of Harrison's spot test was developed by Watson and Hawkinson⁵ in 1946 as a semiquantitative test.

It becomes immediately evident that a simple yet reasonably accurate, quantitative test of bilirubinuria is needed. The value of such a test in the diagnosis and prognosis of hepatic and prehepatic hyperbilirubinemia and in the diagnosis of hepatitis in the preicteric stage is obvious. In order to meet this need the following method is elaborated. It is based on the oxidation of bilirubin to a green derivative and the estimation of the latter spectrophotometrically at a wave length of 670 millimicrons.

METHOD

In this procedure a modified Fouchet's reagent is utilized as an oxidizing agent. This is prepared with 6.25 Gm of trichloroacetic acid and 2 ml of a 10 per cent ferric chloride solution diluted to 200 ml with distilled water. A Coleman Junior spectrophotometer is used with 15 mm cuvettes and adapter. A standard bilirubin solution is prepared by dissolving 10 mg of pure bilirubin in 100 ml of chloroform. To 20 ml of this standard solution are added 80 ml of 95 per cent ethyl alcohol resulting in a 2 mg per cent solution of bilirubin. Further dilutions of the latter solution are made as desired with 95 per cent ethyl alcohol. Into a 15 mm cuvette are placed 4 ml of the chloroform alcohol solution of bilirubin of known concentration, 4 ml of 95 per cent ethyl alcohol and 2 ml of the modified Fouchet's reagent. A reference tube is prepared by adding to 4 ml of 20 per cent chloroform alcohol solution 4 ml of 95 per cent ethyl alcohol and 2 ml of 3.125 per cent trichloroacetic acid. Ten minutes are allowed to elapse after the addition of the modified Fouchet's reagent to permit the full development of the green color. The spectrophotometer is set at a wave length of 660 μ and at 100 per cent transmission with the reference tube. A reading then is taken

From the Laboratory Section, Department of Internal Medicine, St. Louis University School of Medicine.
Received for publication June 1948.

with the bilirubin solution and plotted on semilogarithmic graph paper using per cent transmission as the abscissa and concentration of bilirubin in milligrams per 100 ml as the ordinate. The point is then connected by a straight line to the point—concentration equals 0, transmission equals 100 per cent. The Lambert Beer Law, $c = -K \log T$, will be expressed by the curve represented by this straight line (Fig 1). From this curve the concentration of any similarly oxidized bilirubin solution can be determined if the percentage of transmission is known.

Fig 1

The wave length of 670 $m\mu$ was chosen after the preparation of a spectrotransmission curve using a 2 mg per cent alcohol chloroform solution of bilirubin treated with the reagent as described. The reference was prepared with 8 ml of 20 per cent chloroform alcohol solution plus 2 ml of modified Fouchet's reagent. This curve was plotted from readings made at 25 $m\mu$ intervals from 400 through 700 millimicrons. From this curve it was evident that the ideal wave length was from 650 to 700 millimicrons. After readings were made at 5 $m\mu$ intervals from 650 to 700 $m\mu$, it was found that a wave length of 670 $m\mu$ was most desirable.

PROCEDURE FOR DETERMINING URINARY BILIRUBIN

To 4 ml of undiluted urine in a 15 mm cuvette are added 4 ml of 95 per cent ethyl alcohol and 2 ml of the modified Fouchet's reagent. A reference tube is prepared with 4 ml of urine plus 4 ml of 95 per cent alcohol and 2 ml of 3.125 per cent trichloroacetic acid. After ten minutes a reading is taken in the spectrophotometer at a wave length of 670 $m\mu$, and the concentration of bilirubin is determined from the previously prepared graph.

DISCUSSION

This procedure provides a simple quantitative method for the determination of urinary bilirubin. Attempts at recovery of bilirubin added to the urine were highly successful as can be seen in Table I. The bilirubin was added to the urine in the form of icteric serum, the concentration of which was determined spectrophotometrically by the method of Malloy and Evelyn. The data provided by these determinations serve to confirm the validity of the curve prepared in the foregoing.

TABLE I VARIATION AND PER CENT RECOVERY BY SPECTROPHOTOMETRIC METHOD OF BILIRUBIN ADDED TO URINE

CONCENTRATION OF BILIRUBIN (MG/ML)	RECOVERY OF BILIRUBIN (MG/ML)	VARIATION (MG/ML)	RECOVERY (%)
1.30	1.25	0.05	96

0.16	0.14	0.02	87
0.77	0.75	0.02	97
0.39	0.37	0.06	95
1.00	0.94	0.09	94
1.50	1.41	0.05	94
Mean		0.07	95

The original Fouehet's reagent will yield a green color if used in this procedure. This, however, has a pH of 1 and it was found that a 25 per cent trichloroacetic acid solution (pH 1) if used as a reference also would yield a green color. When the pH of the reagent and reference solution was brought up to 4, no oxidation of the bilirubin to a green derivative took place in the reference tube. The oxidation at this pH apparently is dependent on the ferric chloride.

By using an equal volume of urine in the reference tube any extraneous color resulting from other chromogens is compensated for. The alcohol in no way enhances or interferes with the production of the green color. It has been introduced to free any bilirubin globin that might be present in a proteinuria.

The normal urinary bilirubin concentration has not been studied adequately, but the preliminary studies on random samples of urine of normal patients done in this laboratory agree with those of Naumann⁸ who found it to be less than 0.5 mg per cent.

To date, salicylates are the only substances found to interfere with this test. If present in sufficient concentration they will produce a pink color when the reagent is added.

SUMMARY

A simple and accurate spectrophotometric method for the quantitative determination of urinary bilirubin has been presented. This test is dependent on the production of a green color resulting from the oxidation of bilirubin with an acid ferric chloride reagent. The choice of optimal wave length and the preparation of a standard bilirubin solution are discussed.

A SCHOLANDER MICROMETER BURETTE OF SIMPLE CONSTRUCTION

SAMUEL RAYMOND, PH D, AND HAROLD E C ZIEHLIN, M D
NEW YORK, N Y

THE Scholander micrometer burette has been of value for the precise measurement of the delivery of small volumes of liquid. The original design^{1, 2} specified a micrometer the barrel of which had to be annealed

Fig 1

drilled, and threaded. The use of a micrometer barrel and a minor rearrangement in design eliminates all machine work and reduces glass blowing to a minimum. The result is a simple apparatus easily constructed by anyone with a knowledge of glass blowing at a fraction of the usual cost.

From the Department of Bacteriology and the Department of Dermatology, College of Physicians & Surgeons, Columbia University.

Aided by a grant from the National Institute of Health.

Received for publication April 30, 1948.

The micrometer head used is a Brown & Sharpe No 294 RS. The glass part is made of 1 mm Pyrex capillary tubing and standard 11 mm Pyrex tubing. The latter has a normal internal diameter of 9 mm with a variation of 0.5 millimeter. In order to obtain a close fit between the 11 mm tubing and the micrometer head, the internal diameter of the tubing should be smaller than the shoulder to be inserted. This diameter is then enlarged to the proper size by grinding it internally with emery paper wrapped around a wooden dowel rod until a close fit is obtained. Small variations in diameter can be taken care of by the cementing process.

In order to obtain a satisfactory cemented seal, both parts should be heated to about 145°C , preferably in a thermostatic oven. The inside of the lower end of the mercury chamber is coated with de Khotinsky cement, which will melt at the temperature given. The shoulder of the micrometer head then is fully inserted into the mercury chamber. If this is done properly, a continuous ring of cement will form at the end of the micrometer, effectively sealing off from the mercury chamber any air spaces which may have formed between the metal and the glass.

The seal must be carefully inspected after the apparatus has cooled. Should the ring of cement not be continuous, the defect can be corrected by introducing a small piece of the cement into the mercury chamber through the micrometer head at the proper place and then reheating the apparatus.

The other details of construction will be apparent from the drawing and need no further description.

We have found that heavy grease in the spindle, as suggested by Scholander, occasionally traps air bubbles which are forced into the mercury chamber by the movement of the spindle. We use a small amount of light machine oil to lubricate the micrometer threads. The hydrostatic head of mercury above the chamber effectively prevents air from entering along the spindle. It is essential to maintain this head at 5 cm or more. The glass tip of the burette should be short enough to avoid a siphoning effect.

The burette described delivers volumes as accurately as the original model of Scholander.

A MODIFIED TECHNIQUE FOR THE EXAMINATION OF BODY FLUIDS

OTTO F. KRAUSHAR, M.D. AND JAMES T. BRADBURY, SC.D.
IOWA CITY, IOWA

IN SOME instances a diagnosis of malignant tumor can be made by examining the cellular content of centrifuged sediment from body fluids but the technical difficulty of obtaining a maximal amount of sediment has limited the usefulness of these studies. Schenken and McCord¹ suggested the use of collodion bags suspended in glass centrifuge tubes. Marcuse and Coulter² reported

Fig. 1—Metal centrifuge tubes used to aid in the study of body fluids. A and B show the intact tubes of two sizes. C illustrates the metal tip removed and the appearance of the collodion bag within the tube.

the use of a metal centrifuge tube made up of three separate parts which simplifies the removal of the sediment. The technique described requires twenty-four to thirty-six hours for completion of the examination. It was decided to combine the advantages of these two devices in an effort to make the study of body fluids more simple and rapid.

From the Department of Obstetrics and Gynecology, State University of Iowa.
Received for publication May 17, 1948.

The bottoms were removed from two sets of standard size metal centrifuge tubes and threaded to receive detachable tips. Each tube of the smaller set holds 15 c.c. and each of the larger set accommodates 50 c.c. (see Fig. 1).

In preparation for use, the tip is first detached and a thin film of stopcock grease applied to the inner surface of the tip and to the lower two inches of the inner surface of the barrel. The tip is screwed tightly to the barrel and 2 or 3 c.c. of moderately thick collodion is poured into the tube. With the tube held horizontally and slowly rotated, the entire inner surface is evenly coated with collodion. The excess is drained from the tube and the collodion is partially dried to form a stable film. It is advisable to determine by experience the necessary thickness of the collodion membrane.

The specimen is poured into the tubes and centrifuged at 1,500 revolutions per minute for fifteen to twenty minutes. The detachable metal tip is then slowly unscrewed, leaving the intact collodion sac containing the sediment suspended from the barrel of the tube. A small incision just above the level of the sediment will allow the supernatant fluid to drain with a minimum of turbulence. The collodion tip is then cut off and dropped into Bouin's solution or formalin. After fixation for at least one hour, the block of sediment can be dehydrated, embedded in paraffin, and sectioned like tissue.

If desired, the sediment can be smeared on clean glass slides, fixed immediately in a 1:1 mixture of 95 per cent alcohol and ether, and stained by the Papanicolaou technique. In these cases the collodion tip is removed, inverted on a finger, and the inner surface rubbed on a slide. Even when no sediment is visible, a fair concentration of the cells often can be seen on the smear.

This technique has been especially fruitful in the study of urinary tract lesions, since renal tumors have been detected by examination of small volume washings of cells from the kidney pelvis. It also has been used to concentrate the cells in pleural and ascitic fluids, secretions aspirated from the bronchial tree, and gastric washings.

*If the volume of body fluid is too great to be accommodated by the metal tubes it can be centrifuged in large glass containers and most of the supernatant fluid decanted. The liquid containing the sediment then can be transferred to the special tubes.

STUDIES ON THE DESTRUCTION OF RED BLOOD CELLS

VI THE SPLEEN AS A SOURCE OF A SUBSTANCE CAUSING AGGLUTINATION OF THE RED BLOOD CELLS OF CERTAIN PATIENTS WITH ACQUIRED HEMOLYTIC JAUNDICE BY AN ANTIHUMAN SERUM RABBIT SERUM (COOMBS SERUM)

INTRODUCTION

BOORMAN, Dodd, and Loutit¹ have demonstrated that the immune serum prepared by Coombs, Mourant, and Race² by the injection of human serum (not red cells) into rabbits may be used to distinguish certain types of acquired hemolytic jaundice from congenital hemolytic jaundice. They observed that the washed red blood cells from five patients with acquired hemolytic jaundice were agglutinated by this serum. On the other hand the washed red blood cells from seventeen patients with congenital hemolytic jaundice were not agglutinated. The test was originally developed by Coombs and associates³ for the detection of the incomplete Rh agglutinin on the supposition that such sensitized red blood cells might carry adsorbed antibody globulins. The red blood cells are agglutinated presumably as a physical manifestation of the union of the globulin or other substance on the surface of the red cells with the antibody in the test serum.

Acquired hemolytic jaundice has been reported as an independent acute or chronic entity^{4, 5} or in association with malaria, tuberculosis, cirrhosis of the liver, Hodgkin's disease, leukemia, carcinomatosis, and cysts and tumors of the ovary.^{6, 7} Splenomegaly is often present in such conditions, and splenectomy in some instances, although not necessarily altering the cause of the disease, may be beneficial by decreasing red blood cell destruction. In some cases the agglutination titer of the patient's red blood cells in antihuman serum rabbit serum declines after splenectomy.⁸ Such observations also encountered in our own experience, have raised the question of whether the spleen, which contains both lymphocytes and reticulo-endothelial cells as potential sources of antibodies, might be a source of the substance presumably adhering to the red blood cells of these patients. The principal objective of the experiments reported here was to examine the spleens removed from patients with acquired hemolytic jaundice and various other conditions for the presence of substances possessing an affinity for normal red blood cells.

This investigation was aided in part by a grant from the John and Mary R. Markl Foundation.

Received for publication Aug 1948

METHODS

All spleens were obtained at operation and unless immediately employed in the experimental procedure were frozen at -1°C and preserved at that temperature. Spleens from three patients with acquired hemolytic jaundice and from two patients with thrombocytopenic purpura were studied immediately after splenectomy. Spleens from one patient with acquired hemolytic jaundice, three with congenital hemolytic jaundice, two with thrombocytopenic purpura, three with congestive splenomegaly (Banti's syndrome), and two with Gaucher's disease were studied after being frozen for from one to two years.

A portion of each spleen was finely ground with a domestic meat chopper. The ground pulp obtained from the spleens that were studied immediately after splenectomy was then stirred vigorously with approximately twice its volume of distilled water. The distilled water was then allowed to drain briefly from the pulp through gauze. This procedure was repeated three times, at which point the pulp usually contained no microscopically visible intact red blood cells. Then the splenic pulp was resuspended in normal saline solution which was finally removed by draining through gauze. The pulp was then weighed. In the case of the frozen spleens the effect of the previous freezing and thawing served to destroy the red blood cells present and so rendered treatment with distilled water unnecessary. The absence of red blood cells from the pulp of these spleens was confirmed in each instance by inspection of a small sample under the microscope.

A sample of pulp from each spleen was then incubated for from one to two hours at 37°C with 3 cc of a 40 per cent suspension of either normal Group O Rh negative red blood cells or of red blood cells of the patient's blood group. The red blood cells had previously been carefully washed three times with physiologic salt solution. The amount of splenic pulp employed in each incubation was judged by the amount that was shown not to cause significant hemolysis of the washed red blood cells during a preliminary period of incubation of one hour at 37°C . With the fresh spleens, 12 Gm of pulp were employed. With the previously frozen and thawed spleens, from 15 to 12 Gm of pulp were used. After the incubation period, two or three times the volume of physiologic salt solution was added to the mixture which was then stirred and filtered through gauze one or more times in order to separate the red blood cells from the splenic pulp. The red blood cells obtained were then carefully washed three times with normal physiologic salt solution and finally made up into a 5 per cent suspension in that medium. A control sample of red blood cells was treated in a similar fashion except that it was not added to splenic pulp.

The test for the presence of adsorbed substance was carried out by incubating for one hour at 37°C 0.2 cc of the 5 per cent suspension of red blood cells with 0.2 cc amounts of serial dilutions in physiologic salt solution of an antihuman serum rabbit serum. The rabbit serum was prepared according to the method of Coombs, Mourant, and Race.² Its strength was determined by a modification of the method of Haberman and Hills against a suspension in physiologic salt solution of Rh positive red blood cells which had previously been sensitized with an Rh blocking antibody with a titer of 1:64. The rabbit serum caused microscopic agglutination of the washed cells sensitized with the blocking antibody in a dilution of 1:128*.

At the conclusion of the incubation period each red blood cell suspension was studied microscopically for evidence of agglutination. The control sample of red blood cells was handled in the same fashion except that its agglutinability was determined only with the undiluted test serum. In addition, tests were made of the agglutinating power of the antihuman serum rabbit serum against washed red blood cells derived from the peripheral blood and from the splenic pulp of the four patients with acquired hemolytic jaundice at the time of splenectomy.

RESULTS

Inspection of the data shown in Table I indicates that subsequent to incubation with the splenic pulp from the four patients with acquired hemolytic jaundice, normal washed red blood cells, either Group O Rh negative or belonging

*It is essential that the serum employed in testing the effects of incubation with splenic pulp has a relatively high titer.

to the same blood group as that of the patient, were agglutinated by the anti human serum rabbit serum. Though definite when observed under the microscope, in no instance was the agglutination present when the serum used was diluted. On the other hand, normal red blood cells after similar incubation with the splenic pulp from patients with congenital hemolytic jaundice were

[illegible]

those derived from the peripheral blood of the same patients. Not shown in the tables is the fact that the red blood cells from the splenic pulp and peripheral blood of two additional patients with congenital hemolytic jaundice failed to agglutinate with the test serum. It was noted that the red blood cells from the splenic pulp of the patients with acquired hemolytic jaundice, when suspended in homologous normal serum, showed marked spontaneous agglutination but not when placed in physiologic salt solution. On the other hand, the red blood cells from the splenic pulp of two of the patients with thrombocytopenic purpura showed only rouleau formation when suspended in homologous serum. When 25 per cent human albumin was used instead of the antihuman serum rabbit serum in performing any of the positive agglutination tests already described, it was invariably found to be less sensitive or to be incapable of causing any agglutination.

DISCUSSION

The results of the present experiments indicate that the spleen is a source of a substance which causes the washed red blood cells of certain patients with acquired hemolytic jaundice to be agglutinated by an immune serum developed in rabbits against human serum (Coombs' serum). Presumably this agglutination is due either to the adsorption of a substance on the surface of the red blood cell or to a modification of its surface structure by contact with an active substance in the splenic pulp. On the basis of current assumptions, the agglutination test may be in fact a test for the presence of adsorbed serum globulins. Indeed, the test originally was developed for the detection of blocking antibody on sensitized red blood cells. Even so, this does not necessarily allow the conclusion that the agglutinability of the red blood cells in acquired hemolytic jaundice is the result of an immunologic process in the strict sense, that is, that the patient's red blood cells, acting as an antigen, have in some way caused the development in his own serum of specific* antibody with avidity for the red blood cells. Although this is entirely possible, the seemingly non-specific agglutination of red blood cells, for example by antiserum developed in rabbits against Type 14 pneumococcus¹⁰ or by certain viruses¹¹ with which the animal has had no previous contact, is today too well known to allow so restricted an interpretation. Indeed, perhaps the association with a variety of infections and neoplastic conditions favors the interpretation of a nonspecific adsorption of a substance by the red blood cells.

The antiserum was developed by the injection of human serum into rabbits. The property of agglutinability of the normal red blood cells, however, was probably conferred by the splenic cells rather than by the presence of serum in the splenic pulp. In the first place, the patient's serum was largely removed from the splenic pulp by the numerous washings employed in the preparations made from the fresh spleens. Second, Shen and associates¹² have shown that even forty-eight hour incubation with the serum from one of these patients did

*In this paper the terms specific and nonspecific are used in order to refer to the reaction of an antibody and not to the formation of antibody. Thus an antibody formed in response to antigen A will react specifically with antigen A but may also react nonspecifically with substance B.

not cause normal red blood cells to become agglutinable by the antihuman serum rabbit serum. Third, the demonstration by Dougherty Chase and White¹³ that rabbit lymphocytes contain a globulin identical with normal serum gamma globulin makes it reasonable to suppose that a similar relationship obtains between cells in the human splenic pulp and the human serum used as an antigen in the preparation of the test rabbit serum.

Other evidence that the spleen is a potent source of the substance causing agglutinability of the red blood cells is the fact already cited that splenectomy in some patients with acquired hemolytic jaundice causes a decrease in the agglutinability of the circulating red blood cells. This was the case in two of these patients. Moreover, it was shown here that the washed red blood cells of the patients with acquired hemolytic jaundice when removed from the splenic pulp were always more strongly agglutinated than were those from the general circulation. On the other hand the red blood cells of two patients with congenital hemolytic jaundice, whether derived from the splenic pulp or from the peripheral blood were not agglutinated by the test serum. This negative finding in congenital hemolytic jaundice is particularly significant because there is ample evidence that in this disease the spheroidal red blood cells are selectively retained and sequestered in the splenic pulp.^{14, 15} Consequently if a substance with affinity for the red blood cells was present in this disease ample opportunity must have existed for its action on the red blood cells in the splenic pulp to become apparent. At any rate it is clear that in these cases of acquired hemolytic jaundice in which the patients' circulating red blood cells and especially those in the splenic pulp, exhibited such a property, the spleen possessed a special capacity for causing normal red blood cells also to become agglutinable by the antihuman serum rabbit serum. In view of the short duration (two hours) of the crude exposure of the normal red blood cells to the splenic pulp *in vitro* compared with the prolonged opportunity for contact by the patients' red blood cells *in vivo* it is not surprising that the agglutination of the normal red blood cells was not more pronounced.

The red blood cells in the peripheral blood of the majority of the twelve patients with acquired hemolytic jaundice and a positive Coombs test that have been studied by us have displayed significantly increased mechanical fragility and in some instances increased osmotic fragility as well.¹² These findings indicate that the red blood cells have been damaged and therefore when mechanically fragile are at least unusually susceptible to destruction by the motion of the circulation. The observation that the red blood cells from the splenic pulp exhibited marked agglutination in homologous normal serum is probably the result of the presence of the adsorbed substance that under other circumstances caused the positive Coombs test. This spontaneous agglutinability of the red blood cells in the splenic pulp may be suspected as the basis of the characteristic histologic picture of congestion and infarction in the spleen that has been reported according to Dameshek and Schwartz⁴ by several authors. It is thus possible that the passive adsorption by the red blood cells of a substance produced in the splenic pulp (and probably in other organs) may result in increasing local stagnation and injury to the red blood cells. The course of

the resulting acquired hemolytic anemia may sometimes be favorably altered by interrupting this vicious cycle by removal of the spleen. On the other hand, in other patients with a positive Coombs test splenectomy may not alter the titer or diminish the anemia, presumably because other organs share this function of the spleen.

SUMMARY AND CONCLUSIONS

Incubation of normal red blood cells of compatible blood group with the splenic pulp of four patients with acquired hemolytic jaundice caused these cells to become agglutinable by an undiluted immune serum developed in rabbits against human serum (Coombs' serum). When similar experiments were conducted using spleens from three patients with congenital hemolytic jaundice, three with thrombocytopenic purpura, three with congestive splenomegaly (Banti's syndrome), and two with Gaucher's disease, the results were negative.

Washed red blood cells removed from the splenic pulp of three of the patients with acquired hemolytic jaundice were more strongly agglutinated by the Coombs serum than were those derived from the peripheral blood. Similar experiments made with washed red blood cells derived from the splenic pulp or peripheral blood of two patients with congenital hemolytic jaundice resulted in no agglutination.

Red blood cells removed from the splenic pulp of three patients with acquired hemolytic jaundice exhibited marked spontaneous agglutination in homologous normal serum but not in physiologic salt solution. Similar experiments with red blood cells removed from the splenic pulp of two patients with thrombocytopenic purpura yielded negative results.

It is concluded that the spleen in certain patients with acquired hemolytic jaundice is a source of a substance responsible for the agglutination of the patient's red blood cells by antihuman serum rabbit serum. That the agglutination is probably the result of a reaction between a substance on the red blood cells and an antibody in the rabbit serum developed against human serum neither proves nor disproves that the substance on the red blood cells was elaborated by an immunologic reaction.

It is concluded that the spontaneous agglutination of the patient's red blood cells, especially when derived from the spleen, and the characteristic congestion and infarction of that organ observed by others suggest that in these instances of acquired hemolytic jaundice spontaneous agglutination of the red blood cells is a factor either causing or resulting from stagnation of these cells in the spleen. The resulting injury to the red blood cells is manifest in those that escape from their temporary sequestration in the spleen by the increased osmotic and mechanical fragilities of the circulating red blood cells of the majority of these patients. If not destroyed in the spleen, when mechanically fragile, such red blood cells may well be abnormally susceptible to the trauma of the motion of the circulation.

We are greatly indebted to Dr. Louis K. Diamond and to Dr. B. Harrison Ragle for an opportunity to carry out observations on spleens removed from their patients at operation.

DEMONSTRATION OF HETEROPHILE ANTIBODIES IN THE CEREBROSPINAL FLUID FROM PATIENTS WITH -INFECTIOUS MONONUCLEOSIS

JOSPH K SILBERSTEIN, M A , THEODORE C BERNSTEIN, M D ,
AND THELMA STERN, B A
NEW YORK, N Y

PAUL and Bunnell¹ in 1932 demonstrated a consistent and marked increase of heterophile antibodies in the serum of patients with infectious mononucleosis. Subsequently it was shown^{2, 3, 4} that by absorption methods these sheep hemagglutinins could be differentiated from those present in the sera of normal individuals and in serum diseases. In 1931 Epstein and Dameshek⁵ described a patient with meningo-encephalitis in the course of infectious mononucleosis. Since then there have been many reports of nervous system involvement with this disease.⁶

Several unsuccessful attempts have been made to demonstrate heterophile antibodies in the cerebrospinal fluid of patients with infectious mononucleosis.^{7, 10} It has been emphasized^{11, 12} that there are relatively small amounts of antibodies in the cerebrospinal fluid as compared with those in circulating blood. The purpose of this investigation was to demonstrate heterophile antibodies in the cerebrospinal fluid of patients with infectious mononucleosis by employing large volumes of spinal fluid and dilute sheep erythrocyte suspensions as antigen.

MATERIALS AND METHODS

A 1 per cent washed sheep erythrocyte suspension was prepared and 0.1 ml of it was added to 1 ml and 0.5 ml of fresh spinal fluid in Kahn sized test tubes and shaken. Saline controls were prepared. The tubes were centrifuged for five minutes at 2,500 revolutions per minute and macroscopic agglutination was demonstrated upon resuspending the cells by shaking. Results were recorded from negative to 4 plus, depending upon the degree of agglutination.

A modification of Davidsohn's¹³ absorption method was adopted to study the heterophilic nature of the agglutinins found in cerebrospinal fluid. One milliliter of spinal fluid was placed in Kahn sized test tubes. To one was added 0.5 ml of guinea pig kidney antigen and to the other 0.5 ml of boiled beef erythrocytes. After incubation for ten minutes at 37° C these were centrifuged at 2,500 revolutions per minute for ten minutes. One milliliter of the supernatant fluid of each was then treated in the manner described previously.

EXPERIMENTAL RESULTS

The blood and spinal fluid of six patients with infectious mononucleosis were examined for heterophile antibodies (Table I). Lumbar punctures were done the same day or the day following the demonstration of a blood heterophile

antibody titer. The serum titers ranged from 1 112 through 1 3 5 8 4 with Davidsohn's method and the specificity was verified by his absorption procedure. A parallel series using similar dilutions of serum and the method employed in testing spinal fluids resulted in approximately an eightfold increase in these titers as compared with the usual technique of serum titration. Hemagglutinins from 1 plus to 4 plus were present in the spinal fluids of all these patients and they had the same absorption pattern as those found in the blood. The sera and spinal fluids of these patients were negative for Kahn and Kolmer Wassermann tests. The spinal fluid cell counts were increased in Patients B and C and lymphocytes predominated. No growth was obtained upon culture. The colloidal gold reactions were normal with the exception of Patient B in whom a slight mid zone curve resulted, and this may have been due to the elevated total protein.

In this study 654 routine spinal fluids were examined and nine had demonstrable sheep hemagglutinins. Six of these were from the patients with infectious mononucleosis described previously. The remaining three (0.4 per cent) so-called false positive hemagglutinins included a case of tuberculous meningitis (cerebrospinal fluid elevated protein) one of subarachnoid hemorrhage

(passive transfer of agglutinins), and one of trichinosis. Although the heterophile antibodies in the first two were absorbed with guinea pig kidney extract, the hemagglutinins in the third persisted after this absorption. The heterophile agglutinins in this patient with trichinosis remain unexplained, although the possibility of concomitant infectious mononucleosis exists.

DISCUSSION

A linear relationship does not appear to exist between the blood and cerebrospinal fluid heterophile antibody titers in infectious mononucleosis during the acute phase of illness. However in both the cerebrospinal fluid and blood, the sheep cell agglutinins persisted following guinea pig kidney antigen absorption and were absorbed with boiled beef erythrocytes (Table I). In a preliminary series of experiments the same spinal fluids were tested with human red cells sensitized with the virus of Newcastle disease,¹⁴ and a high degree of nonspecificity was found. Encephalitis associated with infectious mononucleosis as suggested by Tidy¹⁵ was noted only in Patient D whose cerebrospinal fluid hemagglutinins were not significantly higher than the others.

SUMMARY

A simple method is described for the demonstration of heterophile agglutinins in cerebrospinal fluid. Of 654 spinal fluids tested, six from patients with infectious mononucleosis had heterophile antibodies in both blood and cerebrospinal fluid and one of these showed nervous system involvement.

The authors wish to express their appreciation to Dr Morris L. Rakieten for advice and for conducting the experiments with the virus of Newcastle disease.

THE USE OF YEAST PHASE ANTIGENS IN A COMPLEMENT FIXATION TEST FOR HISTOPLASMOSIS

II RESULTS WITH GROUND ANTIGENS

CHARLOTTE C CAMPBELL AND SAMUEL SASLAW MD PH D
WASHINGTON D C

WITH THE ASSISTANCE OF SHIRLEY A KNIBB, B S

A COMPLEMENT fixation test for the detection of antibodies against *Histoplasma capsulatum* employing the yeast phase of the organism as antigen has been described previously from this laboratory¹. In the presence of yeast phase antigens, immune rabbit sera fixed complement in high dilutions, but immunologic cross reactions with *Blastomyces dermatitidis* described by others^{2,4} working with mycelial antigens were noted also in our studies.

Yeast phase antigens described in the earlier report were completely satisfactory for short periods but tended to develop anticomplementary activity after storage for several weeks at 3 to 6° C. Also since in our complement fixation test the per cent hemolysis was determined by comparison with centrifugalized standards, it was occasionally difficult in the range nearing complete hemolysis, to differentiate nonhemolyzed sensitized sheep's cells from the residual sediment of turbid antigens. These minor difficulties instigated the search for an antigen which would meet more adequately the precise end points and demands of the test. This report describes the use of ground yeast phase antigens.

MATERIALS AND METHODS

Antigens—Antigens were prepared from the yeast phase of each of three strains of *H. capsulatum* (G 2 G 5 G 6) and two strains of *B. dermatitidis* (A 1 and A 5†). The yeast phase organisms were obtained from cultures grown at 37° C on glucose cystine agar containing 35 units of penicillin and 40 units of streptomycin per milliliter of medium. After the fifth day of incubation the growth was washed gently with sterile buffered saline from the surface of at least five slants, filtered through sterile gauze and centrifugalized. The sediment was resuspended in 50 ml of sterile buffered saline containing Merthiolate (1:10,000 final concentration) and stored at 37° C. Organisms thus treated were usually not viable after seventy-two hours but since further incubation did not alter the resultant antigen exposure to Merthiolate was continued as a precautionary measure for one week.

The Merthiolate killed suspension was centrifugalized for thirty minutes at 3,000 revolutions per minute, the supernate discarded and the sediment transferred to a small TenBroeck glass tissue grinder. The organisms were then ground by hand for thirty minutes. One to three milliliters of sterile buffered saline were added at five minute intervals during grinding. Finally the ground antigen mixture was centrifugalized until the supernate was completely free of organisms. This clear saline supernate constituted the antigen. The grinding procedure usually was repeated several times with each sediment and the supernates were saved.

From the Department of Bacteriology, Army Medical Department Research and Graduate School, Army Medical Center.
Received for publication July 9, 1948.

The G 2 G 5 and G 6 strains of *H. capsulatum* were reverted from the mycelial phase of strains 715, 95² and 650 respectively from the collection of Dr. V. F. Conant at Duke University, Durham, N. C.

† A 1 strain of *B. dermatitidis* and A 5 (Duke 930) are isolates from human cases received from Dr. Conant at Duke University.

in separate containers. Supernates showing adequate and comparable titers were pooled, while those of reduced or unsatisfactory potency were discarded. After the addition of Merthiolate 1:10,000 as preservative, the pooled material was titrated and used as the stock antigen.

Antisera, diluent, sheep red blood cells, hemolysin, and complement were prepared exactly as described in the previous report¹ and the complement fixation test of Kent and Rein² was again employed.

RESULTS

Experiment 1—The optimal dilution of each lot of antigen was determined by titration. The antigenic unit was established as being the greatest concentration contained in 0.2 ml. beyond which further increase failed to enhance the serum reaction. It was required that this antigen concentration be neither anticomplementary nor hemolytic. The optimal dilutions of the ground antigen

varied between 1:2 to 1:4, and Table I shows a typical titration in which the G-2 antigen was shown to have an optimal dilution of 1:2. As can be seen in Table II, the ground antigens prepared by the described method have been used in this laboratory for twelve consecutive weeks with no development of anticomplementary activity and with no appreciable loss in titer when stored in the refrigerator.

of *B. dermatitidis* were employed against the same antisera. In the presence of the A-5 antigen both the A-1 and A-5 rabbit antisera fixed complement in dilutions of 1 40 (Table V). The G-2, G-5, and G-6 histoplasma antisera fixed complement in dilutions of 1 80, 1 160, and 1 40 respectively. With the exception of the G-5 antisera, the titers of the histoplasma antisera were lower in the presence of the blastomyces antigen than in the presence of their specific antigens (see Tables III and IV). The significance of these results will be discussed below.

DISCUSSION

The preparation of ground yeast phase antigens of *H. capsulatum* and *B. dermatitidis* for use in the complement fixation test is herein described. Rabbit antisera prepared from homologous and heterologous strains of *H. capsulatum* and *B. dermatitidis* fixed complement in the presence of both histoplasma and blastomyces antigens, while sera prepared against *C. albicans*, *S. schenckii*, and *B. brasiliensis* as well as normal rabbit sera did not.

The cross reaction pattern noted when the whole yeast phase organisms of *H. capsulatum* and *B. dermatitidis* were used¹ was even more pronounced with the use of ground yeast phase antigens. The A-1 and A-5 blastomyces antisera having specific titers of 1 40 fixed complement in the presence of ground histoplasma antigens in serum dilutions of 1 20 to 1 40. (With whole organisms this cross had been found only in dilutions of 1 10 or less¹). Evidence that a strong antigenic relationship exists between these two organisms was even more apparent when histoplasma antisera was tested for complement fixing antibodies in the presence of blastomyces ground antigens. Histoplasma sera having specific titers of 1 160 to 1 320 reacted with blastomyces antigens in serum dilutions ranging from 1 40 to 1 160. However, the antiserum against the G 5 strain of *H. capsulatum* fixed complement to the same dilution in the presence of both the specific and *B. dermatitidis* antigens, while the G 2 antiserum with a specific titer of 1 320 fixed complement in the presence of blastomyces antigen only to a dilution of 1 80. This suggests that the common antigenic component of the two organisms may appear in varying degrees in different strains and emphasizes the risk involved in evaluating the results of complement fixation

tests for histoplasmosis which utilize only the antigen of *H capsulatum*. On the other hand, the use of both *H capsulatum* and *B dermatitidis* antigens allows for a more comprehensive and critical analysis of the test proper and of the results obtained thereon.

The ultimate value of the complement fixation test as a potential diagnostic aid in the diagnosis of histoplasmosis in patient material is yet to be determined. Whereas the tests now in use employ histoplasmin, a filtrate of the mycelial form of *H capsulatum*, as antigen, it is our belief at this time that tests aimed toward the detection of antibodies against *H capsulatum* as it appears in pathologic processes that is the yeast phase should be investigated more fully. Immunologic cross reactions occur between blastomyces and histoplasma rabbit antisera regardless of the phase employed as antigen but in our experience the use of histoplasmin as antigen has not been as satisfactory as yeast phase antigens because of its high incidence of anticomplementary activity and the low serum titers obtained.⁷

The use of whole yeast phase organisms as antigens is relatively simple and has been described earlier by us.¹ Ground antigens offer two advantages: (1) a clearer, more readily readable test and (2) greater stability of the antigen. A disadvantage (if it may be called such) of the ground antigen is the greater degree of cross reaction between *H capsulatum* and *B dermatitidis*. This, however, as mentioned, can usually be better evaluated by the judicious use of antigens prepared from both organisms.

SUMMARY

The preparation of ground antigens from the yeast phase of *H capsulatum* and *B dermatitidis* for use in complement fixation is described.

Ground yeast phase antigens are as specific as antigens made from whole organisms; they give more clear cut end points and do not develop anticomplementary activity during storage at 3 to 6° C.

The immunologic relationship between *H capsulatum* and *B dermatitidis* noted in a previous report concerning yeast phase antigens has been confirmed further.

The use of both *H capsulatum* and *B dermatitidis* antigens in evaluating complement fixing antibody responses to *H capsulatum* is recommended.

ANTIGENIC DIFFERENCES AMONG INFLUENZA A VIRUSES, INCLUDING SEROLOGIC RESPONSE OF PATIENTS

HERBERT R. MORGAN, M.D.,* MILDRED W. BARNES, M.S., AND
MAXWELL FINLAND, M.D.
BOSTON, MASS.

THE failure of influenza virus vaccines to protect immunized individuals during the influenza outbreak that occurred early in 1947 and the demonstration of antigenic differences between the strains of virus contained in the vaccines and those responsible for the epidemic^{1,3} have aroused further interest in the problem of strain variations among influenza viruses.^{1,2} Strains of influenza virus were also isolated during the same epidemic when it occurred in Boston, and they too showed sharp differences from the classic PR8 strain of influenza A. The present report presents the results of studies on (1) the antigenic relationships of these recently isolated strains to several that were obtained in a local outbreak in 1943-1944⁶ and to several other well-known strains of influenza viruses and (2) the immunologic response of patients to their homologous virus and to other strains of influenza virus.

MATERIALS AND METHODS

Throat Washings—Garglings were obtained on the first to the third day of the disease from thirteen patients who were acutely ill with clinical influenza and had temperatures of 100° F or higher at the time. The washings were made with infusion broth containing 10 per cent horse serum and were collected between March 18 and April 17, 1947. Most of them were tested for virus immediately and then stored in sealed glass ampules in the dry ice cabinet. Garglings were also obtained from the patient P.W., an isolated instance of clinical influenza, on Dec. 6, 1947, the data on this patient are included in the tables, but will be discussed separately.

Virus Isolation—Attempts were made to isolate influenza viruses from the throat washings, and in two instances from nasal secretions, by inoculation of embryonated eggs by both the amniotic and allantoic routes as previously described.⁷ Once the virus was established, subsequent passages all were made in eggs by the allantoic route.

Serologic Tests—The methods used in the hemagglutination inhibition and complement fixation tests were similar to those used in previous studies.⁶ Serum neutralization tests were carried out in chick embryos by two different methods: one of these employed the allantoic route as described by Hirst,⁸ and the other was a modification in which 0.25 ml. amounts of the serum virus mixtures were injected into the yolk sac of 7 day old eggs which were then incubated for five days at 35° C, the deaths were recorded and the serum protection titers based on the LD₅₀ were calculated.⁹ The latter method eliminated the necessity of opening each egg individually to test for the presence of influenza virus.

Acute (third day or earlier) and convalescent (tenth day or later) phase serum specimens were obtained from the patients and stored at -20° C in rubber stoppered tubes. Rabbit antisera for the study of antigenic differences were prepared against each virus. Albino rabbits, weighing 2.5 to 3.5 kilograms, were first bled to obtain control serum specimens, they were then injected intravenously with 0.1 ml. of virus infected allantoic fluid and bled again after ten to fourteen days. The sera were heated at 60° C for twenty

*Senior Fellow in Medical Sciences, National Research Council.

minutes and tested for antibody by the hemagglutination inhibition method. If a satisfactory rise in titer was obtained the rabbits were bled by cardiac puncture and the serums stored in sealed glass tubes at -20°C until used.

RESULTS

Virus Isolations—Strains of influenza virus were obtained from the throat washings of three patients (E B, G P and D W) of the thirteen from whom washings were obtained during the March-April 1947, outbreak and a strain also was obtained from the nasal secretions of one of them (E B). In each instance the virus was first identified on the second amniotic passage in embryonated eggs and was detected in both amniotic and allantoic fluid at that time*. The throat washings of E B also yielded the virus after four allantoic passages. Each of the remaining throat washings and the other sample of nasal secretions were passed blindly four or five times both by the amniotic and by the allantoic routes without yielding any detectable virus. Two throat washings which had given negative results following passages in embryonated eggs were inoculated intranasally in mice and lung suspensions were passed, three times in one instance and six times in the other, without producing visible lesions.

Thus, influenza viruses were isolated only with difficulty during this outbreak, and the amniotic route of inoculation gave the best results. Similar difficulty in establishing viruses in eggs was also reported by others¹.

Serologic Tests in Patients' Serums—The results of the hemagglutination inhibition and complement fixation tests on the serums of twenty patients who were acutely ill with clinical influenza between the middle of March and the middle of April 1947, and in the case of P W who was ill in December of that year are shown in Table I. It is seen first of all that no significant rises in titer were obtained with the Lee strain of influenza B in any instance. With the other viruses used, both the absolute titers and the extent of the rises in titer varied in the same patient with the different viruses and in a number of instances there were similar discrepancies in the titers obtained with the same virus by the two tests. Some of the latter discrepancies were elicited even when the two tests were done simultaneously with the same serum dilutions and the same virus antigens.

A fourfold or greater rise in titer was obtained by one or both tests with the PR8 strain or with one of the epidemic strains in each of the twenty patients who were ill in the spring. In five of these patients such rises were elicited either by only one of the virus antigens or by only one of the tests, but not with the other test employing the same antigen nor by either test with any of the other virus strains. The serums of one of these patients D W showed a significant rise in titer only by the agglutination inhibition test with one of the epidemic strains GP but showed either no change or only a twofold increase in titer with the other viruses used including the strain isolated from the patient's own throat washings.

The tests with the PR8 strain yielded the greatest proportion of positive results. Only one patient J M, showed no increase at all by the agglutination

* For subsequent serologic tests with rabbit antisera and with patients' serums the viruses were used only after they had been passed through eighteen to twenty additional allantoic passages.

inhibition test with this strain, and the complement fixation test was not done with this patient's serum. In this case a fourfold rise in titer was elicited only by the complement fixation test with one of the epidemic strains EB. Two patients, D W and M P, yielded only a twofold rise in titer by both tests with the PR8 strain, the latter showed a fourfold rise with two of the epidemic strains. Three other patients yielded a fourfold rise by one test with PR8 and a twofold rise by the other test with the same strain. The serums of all of the remaining patients showed a fourfold or greater rise in titer by both tests with the PR8 strain and the increases in titer were greater with this strain than with any of the others used.

Significant rises in titer were less frequent and less striking with the DW strain than with the other two epidemic strains. With each of the epidemic strains, and particularly with the EB strain the complement fixation test yielded an appreciably higher proportion of significant rises in titer than did the agglutination inhibition tests. The rises in titer with the Swine strain were less striking than those obtained with the PR8 or with the epidemic strains.

Antigenic Relationships Among Strains of Influenza Virus—Because of the demonstration in a previous study⁷ that the virus neutralization test is more sensitive than either the hemagglutination inhibition or the complement fixation test for the detection of strain differences the neutralization test with rabbit antiserum was used to study the antigenic relationships of the strains isolated from this outbreak and a number of other strains. The method of Hirst⁸ was used. The following strains of influenza virus were compared: EB, GP, and DW isolated during the outbreak of March-April 1947 in Boston, FM₁ isolated during the epidemic of the same season at Fort Monmouth N. J., MA, MB and CP isolated during the 1943-1944 outbreak in Boston, PW isolated from a sporadic case in Boston in December 1947 and also the well known PR8 Weiss, Swine and Lee strains. The results are shown in Table II.

— Not done.

Strains MA, MB and CP correspond to Case Numbers 63, 4 and 67 respectively in the report of the 1943-1944 epidemic.

†Number of 50 per cent infective doses (ID₅₀) inoculated.

‡Reciprocal of 0 per cent protective titer of serum homologous titer in bold type.

§Titer of homologous rabbit antiserum 512.

None of the control rabbit serums showed any neutralization with any of the serums used, even in the lowest dilution tested, namely 1:4. In the neutralization tests with the immune rabbit serums, the three strains EB, GP, and DW showed sharp differences from the classic PR8, Weiss, and Swine strains of influenza A in that there was little or no cross neutralization. Furthermore, the DW strain was distinctly different in its reaction from the related EB and GP strains, although all three of these viruses were isolated from members of the staff of the Boston City Hospital during the same outbreak. The two latter strains appear to be very closely related to the FM₁ strain isolated at Fort Monmouth during the same season.

The influenza virus strains of the 1947 epidemic showed little or no relationship to the three strains isolated in the 1943-1944 outbreak in Boston. Of the three strains isolated from the latter outbreak, MA shows distinct differences from the classic PR8, Weiss, and Swine strains, MB is related to the PR8 strain, and CP is almost indistinguishable from PR8 in these neutralization tests. Furthermore, strain MA is clearly differentiated from the MB and CP strains, the two latter strains show a considerable degree of relationship to each other, but do not show complete cross reactions.

Neutralization Tests With Patients' Serums—In the light of the demonstration of sharp strain differentiation with rabbit antisera by the serum neutralization test, it was of interest to determine whether this more sensitive test might show greater specificity in the antibody response of the human host than did the agglutination inhibition or complement fixation tests. Selected serums from patients studied during the 1947 outbreak of influenza were, therefore, tested for neutralizing antibody content, using the yolk sac method⁹ for this purpose. The results are presented in Table III.

TABLE III RESULTS OF NEUTRALIZATION TESTS WITH INFLUENZA VIRUSES AND SERUMS OF PATIENTS USING THE YOLK SAC ROUTE OF INFECTION

PATIENTS' SERUMS	VIRUS†				
	EB	GP	DW	FM ₁	PR8

PW	<4/<4	—	<4/<4	<4/<4	<4/<4

— Not done

*Reciprocals of the serum dilutions giving 50 per cent protection (acute/convala-scent)

†Inoculum per egg in most tests was about 50 LD₅₀ (range 32-63) in five days

One striking feature of the results obtained by this method in these patients' serums was the failure of the acute phase serums to neutralize any of the viruses to any significant extent. This is in contrast to the results obtained with the hemagglutination inhibition and complement fixation tests, but corresponds with the results of the neutralization tests in the normal rabbit serums when the allantoic method was used. There were two notable exceptions in that the acute phase serums of patients A A and D N had neutralizing titers of 1:201 and

1:32 respectively for the PR8 strain low titers (1:4 to 1:8) with this strain were found also in the acute phase serums of two additional patients, and similar low titers were obtained in two patients with the FM₁ strain.

Among the epidemic cases, the neutralization of the viruses by the convalescent serums in this small group of adult patients failed to show clean cut or consistent strain differences. In general however, the highest titers and the greatest rises in the neutralizing titers occurred with the PR8 and the FM₁ strains, and this was true irrespective of whether the titers with the epidemic strains were high or low. The serums of D W failed to neutralize any of the local epidemic strains, including the one isolated from this patient's own throat washings but they did show a slight and probably significant rise in titer with the FM₁ strain. One patient, A A failed to show any neutralizing antibodies for the GP strain, but showed a good antibody response to all of the other strains, in another of the epidemic cases that of patient D N only minimal rises were demonstrated with the EB and DW strains and only a slightly better response was obtained for the GP virus.

Results in a Sporadic Case—The throat washings obtained from patient P W on Dec 6, 1947, yielded a strain of influenza virus on several separate attempts. The virus was obtained on one occasion by amniotic inoculation and was first demonstrated in the third amniotic passage. It was also demonstrated on another occasion in the first amniotic passage of the lungs of mice that had been inoculated intranasally with the washings. Both of these strains were subsequently maintained by serial allantoic passage and they gave similar reactions in all tests. The strain obtained directly in eggs was used in the tests listed in Table II. As shown in Table II this virus was neutralized only by its homologous rabbit antiserum but not by the antisera prepared with the Lee strain of influenza B, the 1947 epidemic strains, the 1943-1944 strains nor with any of the standard influenza A strains. The acute and convalescent serum of P W failed to show any antibody response to any of the viruses used by the hemagglutination inhibition or complement fixation tests (Table I) or by the *in ovo* neutralization tests done by the yolk sac method (Table III).

DISCUSSION

The data presented indicate that the outbreak of influenza which occurred in Boston in March and April 1947 was caused by strains of influenza virus which though they resembled the PR8 strain of influenza A, were antigenically distinct from that strain and also from strains isolated in Boston during 1943-1944. Similar observations have now been recorded with respect to outbreaks of influenza which occurred during the same season in other parts of this country and in England.

In addition the strains isolated during this outbreak showed some antigenic differences among themselves as indicated by cross neutralization tests in embryonated eggs with antisera prepared in rabbits. Some differences also were noted in the antibody titers and rises in titer against these strains in the serums of patients both in the *in vitro* tests used and to some extent in the *in ovo* neutralization tests done by the yolk sac method. Similar antigenic differences

also have been demonstrated among the strains isolated during the influenza epidemic in Boston in 1943-1944. The latter strains showed somewhat greater resemblance to the PR8 strain. Distinct antigenic differences among influenza B strains isolated during a single outbreak also have been demonstrated.⁷

Of particular interest were the occasional patients like D W who was ill during the height of the outbreak and P W who was ill in December when no other cases of influenza virus infection were established in this area. In these patients' serums little or no antibody response was detected, either with the standard strains of influenza virus or even with the strains isolated from their own throat washings. Similar observations previously have been made in several patients ill with clinical influenza shortly after the influenza A epidemic of 1943-1944.⁶ Strains MA and CP were obtained from such cases during the latter outbreak.

In view of the distinct antigenic differentiation between the epidemic strains isolated in the spring of 1947 and the PR8 strain, it is also of interest that during this outbreak better antibody responses were elicited in the patients against the PR8 strain than against the strains isolated during this epidemic. This was true even in the patients from whom the viruses were isolated. Similar results were obtained during the same season in England.⁴ In the present study this lack of specificity in the serologic response of adult patients was demonstrated, both by the *in vitro* tests (hemagglutination inhibition and complement fixation) and by the *in ovo* neutralization tests done by the yolk sac method. In the latter tests this was true in spite of the fact that all of the acute phase serums gave completely negative results with the three local epidemic strains. In the rabbit antiserums, on the other hand, the neutralization test permitted much more definite antigenic differentiation among the strains and proved much more satisfactory than *in vitro* tests for that purpose.

SUMMARY AND CONCLUSIONS

Strains of virus isolated from patients during the epidemic of influenza which occurred in Boston in March-April, 1947, were shown to be antigenically distinct from several classic strains of influenza A and from strains of influenza virus isolated in Boston during and shortly after the 1943-1944 epidemic. The strains from both of the epidemics, however, showed some antigenic relationship to the PR8 strain of influenza A, but not to the Lee strain of influenza B.

Evidence was presented which suggested that at least two antigenically distinct strains of influenza virus were active during the 1947 epidemic, one of them closely resembled the FM₁ strain isolated elsewhere during the same season. Antigenic differences were also demonstrated among strains of influenza A isolated in Boston during and after the outbreak of 1943-1944.

During the 1947 outbreak, higher titers and greater rises in titer of influenza antibodies were elicited in the serums of patients with the PR8 strain than with the epidemic strains.

A strain of virus isolated from a sporadic case of clinical influenza in December, 1947, showed no antigenic relationship to any of the influenza viruses included in this study. Antibodies against this strain could not be demonstrated in the serum of the patient from whom it was isolated.

STUDIES ON CARDIOLIPIN ANTIGEN

IV VARIATIONS IN SENSITIVITY OF DIFFERENT LOTS OF PURIFIED LECITHIN

REUBEN L. KAHN AND ELIZABETH B. McDERMOTT

ANN ARBOR, MICH.

IT WAS observed early that different lots of cardiolipin antigen prepared according to the same formula gave inconstant results in the standard Kahn test. The question arose whether the variable factor was present in the cardiolipin, the purified lecithin, or in both. This article briefly summarizes our serologic results based on the use of different lots of cardiolipin and lecithin.

Table I illustrates differences in sensitivity of two different lots of cardiolipin antigen in the standard Kahn test. The antigens were prepared according to a previously employed formula, namely, 0.75 per cent purified lecithin, 0.03 per cent cardiolipin, and 0.1 per cent cholesterol¹. To this antigen was added 0.2 ml. of a 10 per cent solution of gum mastic (N. F.) in absolute alcohol. The titer with 0.9 per cent NaCl solution was the same with both antigens, namely, 1 plus 11. Standard Kahn tests were performed mainly with weakly positive syphilitic serums. Two readings of results were made, the first immediately after the addition of diluent (salt solution), and the second fifteen minutes later. A summation of plus signs of the readings of the three-tube tests with each antigen shows that cardiolipin antigen Lot P gave, on first and second readings, a total of 121 and 105 plus signs respectively, while antigen Lot L gave on first and second readings a total of 179 and 161 plus signs respectively. Thus, antigen Lot L was obviously more sensitive than antigen Lot P in the simultaneous examination of twenty-five serums.

This finding raised the question whether these differences in sensitivity were due to differences in cardiolipin or in purified lecithin. Table II illustrates standard Kahn results with antigens prepared with three different lots of cardiolipin and one lot of purified lecithin (Lot IA-46). Ten weakly positive serums were employed. The antigen containing cardiolipin Lot 42 gave, on first and second readings, a total of 45 and 42 pluses respectively. The antigen with cardiolipin Lot Run 3 gave, on first and second readings, a total of 43 and 42 pluses respectively. The antigen with cardiolipin Lot 35-37 gave, on first and second readings, 44 and 41 pluses respectively. It is thus evident that the three lots of antigen prepared with different lots of cardiolipin gave, with a single lot of purified lecithin, closely parallel Kahn results with weakly positive serums.

When turning to antigens containing different lots of purified lecithin with one lot of cardiolipin, the Kahn results were found to be of a different nature,

From the Serology Laboratory, University Hospital, University of Michigan.

Aided by a grant from the Difco Laboratories, Detroit, Mich.

Cardiolipin and purified lecithin employed in this study were kindly supplied by the Lederle Laboratories, Pearl River, N. Y., and by Dr. Mary Pangborn, New York State Department of Health, Albany, N. Y.

Received for publication July 14, 1948.

*One reading of the tests was made namely immediately after the addition of diluent.

It seemed worth while to serologically examine different antigens containing different lots of lecithin with still another lot of cardiolipin. Lot L instead of Lot P employed in the previous experiment. Table IV summarizes the results of this comparison. The antigen with lecithin Lot 1A 46 gave in the Kahn test 38 pluses on the first reading, and 35 pluses on the second reading. The antigen with lecithin Lot Run 3 gave 63 pluses on the first reading and 55 pluses on the second reading. The antigen with lecithin Lot Run 4 gave on first and second readings, 52 and 46 pluses respectively.

A similar experiment in which two different lots of lecithin were employed with two different lots of cardiolipin in accordance with our latest formula in which 10 per cent lecithin is employed with 0.1 per cent cardiolipin and 0.025 per cent cholesterol is illustrated in Table V. No mastix was employed in this formula. It is evident from Table V that cardiolipin antigen containing Lecithin Lot 11 gave, with ten weakly positive serums a total of 56 plus signs while cardiolipin antigen containing lecithin Lot 17 gave with the same serums a total of 37 plus signs.

It is thus clear that different lots of purified lecithin in cardiolipin antigen may cause the antigen to vary in sensitivity to the extent of 40 per cent or more. These differences can be noted best when weakly positive reacting serums are employed.

Preliminary standardization methods developed in this laboratory for cardiolipin antigen indicate that many purified lecithins will become usable by variations in the ratio of lecithin to cardiolipin within certain limits. Thus with the employment of a 10:1 ratio of lecithin:cardiolipin as a working base a reduction in lecithin, such as 9:1 tends to decrease sensitivity while an increase in lecithin such as 11:1 tends to increase sensitivity.³

SUMMARY

It was observed that different cardiolipin antigens, prepared according to the same formula but consisting of different lots of cardiolipin were of uniform sensitivity in the standard Kahn test. When the cardiolipin antigens were prepared with different lots of purified lecithin considerable variations in sensitivity were noted. This finding indicates that cardiolipin antigens prepared with different lots of purified lecithin require serologic standardization before their employment in tests for syphilis.

STUDIES ON CARDIOLIPIN ANTIGEN

V STANDARDIZATION OF ANTIGEN FOR THE KAHN TEST

ELIZABETH B McDERMOTT AND REUBEN L KAHN
ANN ARBOR, MICH

THIS article deals with various aspects of the standardization of cardiolipin antigen for the standard Kahn test. Preliminary studies with this antigen indicated that it behaves essentially like Kahn antigen in its titration with salt solution. These studies further indicated that in the final standardization of cardiolipin antigen for use with serum this antigen also behaves essentially like Kahn antigen. Hence, many technical steps developed in connection with the titration and standardization of Kahn antigen were found to be applicable to the titration and standardization of cardiolipin antigen. The major aim of standardization of cardiolipin antigen is of course the same as that of the standardization of Kahn antigen, namely, to assure uniformity in serologic results with syphilitic and nonsyphilitic serums.

The Need of Standardization of Cardiolipin Antigen—Tissue extract antigen, such as Kahn antigen, requires three steps in its standardization: (1) The titration of the antigen with salt solution to determine the titer at which the antigen is to be mixed with salt solution in the preparation of the antigen suspension for use with serum. (2) Comparative tests with syphilitic and non-syphilitic serums, employing standard antigen as a control, to determine how closely a new antigen behaves like standard antigen in sensitivity and specificity. (3) Adjustment or correction of the new antigen if in its behavior with serums it is either oversensitive or undersensitive as compared with standard antigen. These three steps are necessary also in the standardization of cardiolipin antigen.

The question might arise why an antigen consisting of purified chemical reagents should need to be standardized. The need for standardization of cardiolipin antigen was pointed out in the preceding article,¹ namely, different lots of purified lecithin do not give rise to identical serologic results.

A Workable Cardiolipin Antigen Formula for the Standard Kahn Test—In attempting to develop a workable cardiolipin antigen formula for the standard Kahn test, various ratios of lecithin-cardiolipin were tried. A 25:1 ratio of these reagents first was reported with the use of a very small amount of mastic.² With the abandonment of this colloid, that ratio was found to be unsuitable for the standard Kahn test. A 20:1 ratio of lecithin-cardiolipin was then tried. Tabular results of cardiolipin antigens prepared with this ratio in their behavior with salt solution will be presented later. At present it is merely desired to state that a 10:1 ratio of lecithin-cardiolipin was found to be suitable as a working base, provided the concentration of these reagents is taken into consideration.^{3, 4}

Cardiolipin and purified lecithin employed in this study were kindly supplied by the Lederle Laboratories, Pearl River, N. Y., and by Dr. Mary Pangborn, New York State Department of Health, Albany, N. Y.

Received for publication July 14, 1948

The proper concentration of lipids plays an important role in the behavior of Kahn antigen with salt solution and with serums and it is understandable that it would also play an important role in the behavior of cardiolipin antigen. Indeed several years' trial of adjusting cardiolipin antigen to the standard Kahn test led to failure until proper concentration of reagents began to be employed. The relationship between lecithin cardiolipin ratios and the concentration of these reagents will be discussed below. First it is desired to present the basic cardiolipin antigen formula employed.

The use of the following percentages of cardiolipin, purified lecithin and cholesterol results in a cardiolipin antigen which behaves broadly like Kahn antigen both in its titration with salt solution and in its reactions with serum.

Purified lecithin	10 per cent
Cardiolipin	0.1 per cent
Cholesterol	0.025 per cent

An outstanding feature of this formula is the relatively high concentrations of cardiolipin and lecithin and the very low concentration of cholesterol. It is believed that the 25 mg per cent of cholesterol in cardiolipin antigen matched against the 600 mg per cent of cholesterol in Kahn antigen might help to bring out selective reactivities of the two antigens in certain situations in syphilis.

Determination of Cardiolipin Antigen Titer—Those who are familiar with the Kahn technique⁵ will recall that when 1 ml of the antigen is mixed with an appropriate amount of salt solution an antigen suspension is produced containing lipid aggregates. An important characteristic of these aggregates is that they are dispersible in salt solution and in serum; then in syphilitic serum new floccules appear, while in nonsyphilitic serum no floccules appear. Essentially cardiolipin antigen behaves the same way with salt solution. When appropriately mixed with salt solution an antigen suspension is produced in which the lipid aggregates are dispersible in salt solution and in serum. Then as in the case of the Kahn antigen suspension floccules appear in syphilitic serum and no floccules appear in nonsyphilitic serum.

The titer of Kahn antigen, by definition, is the smallest amount of salt solution added to 1 ml of antigen which will produce a lipid suspension containing dispersible aggregates. The same definition applies to cardiolipin antigen. However, after the titer has been obtained it is not necessarily true that either antigen at the titer will give correct results with serum. The sensitivity of the titrated antigens with serums must be determined by trial.

Briefly, the basic requirements of an antigen suspension at its titer for use in tests with serum are as follows:

- (1) The antigen suspension must contain a minimal amount of salt solution; an increase in the salt solution beyond the titer tends to reduce sensitivity and a decrease in the salt solution below the titer tends to increase sensitivity and nonspecificity.

- (2) The lipid aggregates of the antigen suspension must disperse in salt solution and in serum.

(3) When these aggregates are thus dispersed in serum, the negative reactions appear opalescent—not suggestive of cloudiness on the one hand or of water clarity on the other. The positive reactions will then show floccules of sufficient bulk as to be readily differentiable.

(4) If an antigen at its titer does not give results comparable to standardized Kahn antigen, special standardization methods are applied with a view toward bringing the antigen to standard sensitivity.

Table I illustrates the titration pictures of cardiolipin and Kahn antigens. The similarity in the titration picture of two antigens is evident. Also evident is the fact that cardiolipin antigen exhibits a narrow titration range with salt solution, while Kahn antigen exhibits a relatively wide titration range. As is illustrated in Table I, the Kahn antigen has a titer of 1 plus 13, while the cardiolipin antigen has a titer of 1 plus 0.9. When 1 ml of cardiolipin antigen is mixed with 0.8 ml salt solution instead of 0.9 ml, the resulting antigen suspension gives cloudy mixtures with serum and it is impossible to differentiate syphilitic from nonsyphilitic serums. If 1 ml of the antigen is mixed with 1 ml of salt solution, the resulting antigen suspension gives altogether too clear mixtures with serum and the suspension is of markedly reduced sensitivity. Briefly, cardiolipin antigen must be mixed with salt solution precisely at the titer, namely 1 plus 0.9, to obtain a usable antigen suspension in which syphilitic serums will show precipitates and nonsyphilitic serums will show the opalescence and clarity characteristic of negative reactions.

TABLE I SIMILARITY OF TITRATION PICTURES OF CARDIOLIPIN AND KAHN ANTIGENS

CARDIOLIPIN ANTIGEN SUSPENSIONS AMOUNTS OF ANTIGEN AND 0.9 PER CENT SALT SOLUTION (ML)	DISPERSIBILITY OF ANTIGEN SUSPENSION AGGREGATES, RESULTS IN 3 TUBE TEST, USING SALT SOLUTION INSTEAD OF SERUM	KAHN ANTIGEN SUSPENSIONS AMOUNTS OF ANTIGEN AND 0.9 PER CENT SALT SOLUTION (ML)
1 + 0.8	Cloudy, nondispersible aggregates	1 + 11
1 + 0.9*	Opalescent (titer), dispersible aggregates	1 + 13*
1 + 1.0	Too clear, dispersible aggregates	1 + 15
1 + 1.1	Much too clear, dispersible aggregates	1 + 17
1 + 1.2	Water clear, dispersible aggregates	1 + 19

*Antigen titers employed in the Kahn test

Cardiolipin antigen Lot C11 L16-AA Kahn antigen Lot 107A

Kahn antigen, on the other hand, is likely to give results closely similar to those given at a titer of 1 plus 13 when the antigen suspensions are prepared by adding 1.2 ml salt solution to 1 ml of antigen or 1.4 ml of salt solution to 1 ml of antigen. Briefly, 0.1 ml of salt solution above or below the titration end point apparently does not markedly affect the physical properties of Kahn antigen suspensions.

This difference between Kahn and cardiolipin antigen is based on the probability that Kahn antigen contains nonantigenic colloids which are protective in nature, while cardiolipin antigen, because of its high purity, lacks these protective colloids. Fig 1 graphically illustrates the narrow titration range of cardiolipin antigen as compared with the relatively wide titration range of Kahn antigen.

Fig 1—Graph illustrating antigen suspension of correct titer in relation to suspensions that give either too clear or too cloudy results

Table II shows that a titer of cardiolipin antigen prepared in a 10:1 ratio of lecithin:cardiolipin is obtainable only under conditions of the appropriate concentration of these reagents. When employing the same ratios of lecithin:cardiolipin, namely 10:1, but in different concentrations of these reagents, workable titers are not obtained. For example, 0.5 per cent of lecithin and 0.05 per cent of cardiolipin do not lead to a workable titer. The same holds true if 2.0 per cent lecithin and 0.2 per cent cardiolipin are employed. Evidently the 10:1 ratio of lecithin to cardiolipin in combination with the appropriate concentration of these reagents is of importance in obtaining a workable cardiolipin antigen titer for the Kahn test.

TABLE II CONCENTRATIONS OF LECITHIN AND CARDIOLIPIN (10:1 RATIO) PRODUCING AN ANTIGEN SUSPENSION USABLE IN THE STANDARD KAHN TEST

ANTIGEN PLUS SALT SOLUTION (ML.)	CARDIOLIPIN ANTIGEN FORMULA		
	A	B	C
	0.5% LECITHIN 0.05% CARDIOLIPIN 0.025% CHOLESTEROL	1.0% LECITHIN 0.1% CARDIOLIPIN 0.025% CHOLESTEROL	2.0% LECITHIN 0.2% CARDIOLIPIN 0.025% CHOLESTEROL

*A usable antigen suspension was obtained when employing 1 ml antigen plus 0.9 ml salt solution

may be found usable with 0.05 per cent cholesterol, but none thus far have given satisfactory titration results with 1.0 per cent cholesterol.

The Titer in Relation to the Sensitivity of Cardiolipin Antigen—It was already indicated that an antigen at its titer may not necessarily give correct sensitivity results. Table V shows that cardiolipin antigens containing lecithins not approved by Dr Pangborn,* may give titration results identical to those of antigens containing approved lots of lecithin. It is evident from Table V that lecithin Lots 12A and 13 gave satisfactory titration results similar to results of approved lots of lecithin.

TABLE V. UNIFORMITY OF TITRATION RESULTS OF SEVEN LOTS OF CARDIOLIPIN ANTIGEN EMPLOYING SEVEN DIFFERENT LOTS OF CARDIOLIPIN AND FIVE DIFFERENT LOTS OF LECITHIN, FORMULA 1 PER CENT LECITHIN, 0.1 PER CENT CARDIOLIPIN, AND 0.025 PER CENT CHOLESTEROL

In attempting to bring the sensitivity of different lots of cardiolipin antigen to a standard level, it was observed that this can be achieved with certain lots of lecithin by merely altering the ratio of lecithin-cardiolipin. If instead of employing a 10:1 ratio of lecithin-cardiolipin, an 11:1 ratio is employed, increased sensitivity is generally obtained. If, on the other hand, a 9:1 ratio of lecithin-cardiolipin is employed, the sensitivity is generally decreased as compared with the 10:1 ratio. Table VII illustrates the sensitivity results obtained on increasing the amount of lecithin above the 10:1 ratio and on decreasing the amount of lecithin below this ratio.

Occasionally it may be found that the change in the lecithin-cardiolipin ratios from 10:1 to 9:1 or 11:1 may lead to sensitivity results beyond those of standard sensitivity. In such instances one should try ratios of 9.5:1 or 10.5:1 as the case may be. Table VIII illustrates the correction of a new lot of cardiolipin antigen, undersensitive in a 10:1 ratio, by employing a 10.7:1 ratio.

It is believed that modification of the lecithin-cardiolipin ratio will not, by itself, correct all undersensitive cardiolipin antigens. It is likely that a small change in the titer, such as a slight reduction in the amount of salt solution in the preparation of the antigen suspension, will increase sensitivity. An increase in the amount of cholesterol in the antigen should also increase sensitivity. Furthermore, adjustment of the concentrations of the lecithin and cardiolipin should play a role in sensitivity. These several steps should make possible the bringing of certain undersensitive cardiolipin antigens to standard sensitivity. In view of the limited availability of cardiolipin antigens with different lecithins, it has not yet been possible to investigate all methods which may increase the sensitivity of cardiolipin antigen. It should be added that cardiolipin antigen in the standard Kahn test, in the present state of our knowledge of this antigen, is employed in this laboratory only supplementary to Kahn antigen.

SUMMARY

Standardization methods applicable to Kahn antigen for use in the standard Kahn test are broadly applicable also to cardiolipin antigen for use in this test. The titer of cardiolipin antigen with salt solution is obtained according to the same procedure as the Kahn antigen titer. The technique for establishing the sensitivity of cardiolipin antigen with syphilitic and non-syphilitic serums is also similar to the technique for establishing the sensitivity of Kahn antigen. Techniques for the standardization of cardiolipin antigen to help provide uniformity in results are presented in this article.

ONE of the greatest disadvantages of penicillin is its rapid elimination from the body. In order to decrease the frequency of injections many attempts have been made to delay the absorption or excretion of penicillin and thus prolong the action of an injected dose. Until recently the most successful method of prolonging the concentrations of penicillin in the blood has been the incorporation of penicillin in peanut oil and beeswax¹. With this preparation a single injection of 1 c.c. containing 300,000 units of penicillin was usually followed by assayable blood concentrations for twenty-four hours in 90 to 92 per cent of patients. The introduction of a fluid preparation obviated some of the difficulties inherent in the administration of this material². Fluid penicillin in peanut oil and beeswax was found to be as effective as the original viscid preparation when 50 per cent of the total relative weight is made up of particles of 50 μ or more in length³. Discomfort to the patient in the form of local pain, tenderness, and nodule formation at the site of injection, however, still persisted.

For some time it has been known that a mixture of concentrated solutions of penicillin and procaine resulted in the formation of crystals which were identified as the procaine salt of penicillin. Whereas the commercially available salts (sodium, potassium, and calcium) are highly soluble in aqueous solutions and body fluids, the procaine salt is relatively insoluble. This property forms the basis of a new principle of penicillin administration. As a result of the low solubility of procaine penicillin, a repository injection of a suspension of this salt in oil or water results in delayed absorption and prolonged blood concentrations. This report presents the results of our studies on absorption following the intramuscular injection of procaine penicillin and the treatment of patients with various infections when procaine penicillin in oil was used.

MATERIALS

Crystalline procaine penicillin is usually prepared by the double decomposition of sodium penicillin G and procaine hydrochloride. The original commercial preparations were suspended in refined sesame or peanut oil so that 300,000 units were present in 1 c.c. as a free flowing fluid material. Such a preparation need not be refrigerated since it will remain stable for at least one year at room temperature. Because the procaine penicillin on standing separates from the oil and because of the necessity for vigorous agitation in

order to reestablish the suspension detergents such as Tween 80 and Span 80† have been added to facilitate resuspension. These measures have been only partially successful. Other investigators have added aluminum monostearate to the mixture to maintain the suspension. The addition of aluminum monostearate to procaine penicillin in oil results in a gel formation which maintains the suspension of the penicillin in the oil.

Peanut or sesame oil was originally employed as a vehicle for injecting procaine penicillin since it was impossible to prepare injectable water suspensions of this penicillin salt. Recently it has been demonstrated that the addition of dried sodium carboxymethylcellulose to dry crystalline procaine penicillin results in a stable suspension in diluents containing water. Sodium carboxymethylcellulose in aqueous solution forms a viscous gel which maintains the procaine penicillin in discrete particulate suspension. This has eliminated the necessity for the use of oils which have been shown to be antigenic and which may cause serious complications if they are injected accidentally into a blood vessel.

All of the procaine penicillin preparations can be withdrawn from the vial and administered through a 19 or 20 gauge needle. For the preparations containing aluminum monostearate or sodium carboxymethylcellulose dry syringes and needles are not needed. When procaine penicillin in oil is administered, moist needles and syringes may be used if the injection is made immediately after the syringe is filled. Although we have given multiple injections of procaine penicillin in oil from a single syringe without difficulty provided the withdrawal and injections were made within a very few minutes these precautions are not necessary with the preparations containing aluminum monostearate or sodium carboxymethylcellulose.

STUDIES ON ABSORPTION

The concentrations of penicillin in the blood at various intervals were determined according to the method of Raudall and associates⁷ following the intramuscular injection of (1) procaine penicillin in oil,‡ (2) procaine penicillin in oil plus aluminum monostearate,§ and (3) procaine penicillin plus sodium carboxymethylcellulose in aqueous suspension||. The results are expressed both as percentage of patients having assayable concentrations (0.3 units per cubic centimeter or more) and as the median concentrations at the various intervals tested.

As shown in Table I all of the patients who received a single or initial injection of 300,000 units of procaine penicillin in oil (1 cc) had detectable levels at one, four, twelve, sixteen, and twenty hours. Only an occasional patient failed to have an assayable level at the twenty-fourth hour. About one half of the patients had measurable levels at the thirty-sixth hour and about one third at the forty-eighth hour. The median levels at various hours are also shown in Table I.

While this study was in progress, several of the commercially available lots of procaine penicillin in oil were found to be inferior in that only about one half to one third of the patients had detectable levels in the blood at the twenty-fourth hour following the injection of 300,000 units of procaine penicillin in oil (1 cc)⁸. It was found that in conversion to mass production crystallization was not carefully controlled, so that large particles of procaine penicillin were

Procaine penicillin in oil	Median levels (U/cc)	0.375	0.375	0.25	0.125	0.031	0.031						
	Percentage of patients with assayable levels*	100	100	100	96	57	36						
Procaine penicillin (particles less than 5 μ) in oil plus aluminum monostearate	Median levels (U/cc)				0.25		0.125		0.062	0.062	0.031	0	
	Percentage of patients with assayable levels*				100		100		100	100	100	42	
Procaine penicillin plus sodium carboxymethylcellulose	Median levels (U/cc)	0.5	0.25	0.25	0.125	0.125	0.062	0.062	0				
	Percentage of patients with assayable levels*	100	100	100	100	100	100	100	25				

At least twenty-five patients were studied at each time interval indicated for the various preparations

*Method of Randall and associates, detecting 0.03 unit per cubic centimeter and higher

produced. In grinding these particles to sizes capable of passage through 19 or 20 gauge needles, relatively large amounts of procaine penicillin dust or flour were produced. The fine particles comprising this dust or flour are dissolved and absorbed relatively rapidly so that prolonged blood concentrations are not maintained. (The manufacturers have taken steps to eliminate the fine particles from their preparations.) Therefore the blood concentrations obtained after the injection of preparations of this kind are not included in Table I.

The percentage of patients and the median blood concentrations following the injection of 300,000 units of procaine penicillin in oil plus 2 per cent W/V aluminum monostearate are also shown in Table I. It is apparent that the addition of aluminum monostearate not only stabilizes the suspension of procaine penicillin in oil but also results in prolongation of the concentrations of penicillin in the blood. Preparations containing particles of penicillin less than 5μ in size resulted in measurable blood concentrations in all patients at twenty-four, forty-eight, seventy-two, ninety-six, and one hundred twenty hours after injection. When large particle procaine penicillin crystals are employed in this mixture the concentrations of penicillin in the blood are not so prolonged.^{4,9}

Fig 1—Curves of the concentration of penicillin in the blood following intramuscular injection of 300 000 units of procaine penicillin G suspended in various vehicles

Included in Table I are the data obtained following the injection of 300,000 units of procaine penicillin plus 3.5 Gm of sodium carboxymethylcellulose contained in 1 cc of aqueous solution. All of the patients studied had measurable levels at sixteen, twenty, twenty-four, thirty-six, forty-eight, and sixty hours. Twenty-five per cent had assayable levels at seventy-two hours.

The median concentrations at the various intervals for all three preparations have been plotted in Fig 1.

Blood concentrations were determined in seventeen patients who were receiving 300 000 units of the procaine penicillin in oil preparations every twelve hours and in fourteen subjects who received 600 000 units (2 cc) every twelve hours. Upon such regimens the blood concentrations at the twelfth hour were at least 0.125 unit per cubic centimeter and usually 0.25 and 0.5 unit per cubic centimeter. There were no significant differences between the two doses.

CLINICAL STUDY

We have treated 251 patients with various infections with procaine penicillin in oil. All the patients received plain procaine penicillin in oil except the patients with gonorrhea who were treated with the material containing aluminum monostearate. The results and plans of therapy are summarized in Table II.

Eighty-nine patients with pneumococcal pneumonia of known type or with findings and a course characteristic of pneumococcal pneumonia were treated with 600,000 units of procaine penicillin in oil (2 cc) every twelve hours until they were essentially afebrile for forty-eight to seventy-two hours. The course was similar to that seen with the use of other penicillin preparations, and recovery was uneventful in all patients. These large doses were employed as a part of a study to evaluate the effect of massive doses in pneumonia. Other investigators¹⁰ have found that 300,000 units a day for similar periods give satisfactory results.

TABLE II DOSAGE SCHEDULES AND RESULTS OF TREATMENT OF VARIOUS INFECTIONS WITH PROCAINE PENICILLIN IN OIL

DISEASE	NUMBER OF PATIENTS	DOSAGE SCHEDULE	COMMENT
Pneumonia	89	600,000 units b i d until essentially afebrile for 48 to 72 hours	Recovered
Typed 41			
Untyped 48			
Acute bronchitis	2	300,000 to 600,000 units b i d for 5 days	Recovered
Acute sinusitis	3	300,000 to 600,000 units b i d for 5 days	Recovered
Tonsillitis	3	300,000 units per day for 5 days	Recovered
Scarlet fever	17	300,000 units per day for 5 days	Recovered
Vincent's infection	1	300,000 units per day for 2 days	Recovered
Infectious arthritis	3	300,000 to 600,000 units b i d for 7 to 10 days	Recovered
Gonococcal 2			
Unknown 1			
Gonorrhea*	57	300,000 units	Only 1 patient had return of symptoms—possible reinfection
Syphilis	75	600,000 units per day for 5 days	All patients showed complete healing of lesions and decrease in serologic titers during 2 to 5 month follow up period
Cellulitis	1	600,000 units per day for 4 days	Recovered
Typhoid fever	1	300,000 units every 6 hours, with sulfathiazole—6 Gm initial dose and 1 Gm every 4 hours	No improvement

*Patients treated with procaine penicillin in oil plus aluminum monostearate

In previous publications^{11, 12, 13} the efficacy of penicillin in the treatment of scarlet fever has been reported. Procaine penicillin in oil in doses of 300,000 units per day for five days has resulted in prompt recovery from this streptococcal infection without pyogenic complications in all seventeen patients treated.

Three patients with bacterial arthritis were treated. Two were considered to have had gonococcal arthritis, since gonococci were isolated from a coexistent

urethral discharge One of the patients was treated with 300,000 units of procaine penicillin in oil every twelve hours Only slight improvement was noted after five days at which time the dose was increased to 600 000 units every twelve hours and rapid improvement ensued The second patient received 300 000 units every twelve hours for seven days with good results These patients are included in a recent report ¹⁴ The third patient was a young colored woman, six months pregnant, who had a profuse vaginal discharge and arthritis of the wrists Gonococci were not isolated from cultures of the vaginal discharge The patient was given 300,000 units of procaine penicillin in oil every twelve hours for seven days with rapid regression of the cervicitis and arthritis

Two patients with acute bacterial rhinohetitis and three with acute sinusitis have been treated successfully One of the patients with acute sinusitis also had acute catarrhal otitis media, the causative organism being a pneumococcus Type 4 This patient was given 600 000 units (2 cc) of procaine penicillin in oil per day for four days The temperature dropped to normal within twelve hours the nasal discharge became less purulent and viscid and was gone at the time treatment was discontinued

A patient with Vincent's infection of the mouth received 300 000 units per day for three days Relief from soreness was reported within twelve hours and the gums appeared normal at the forty eighth hour

Three patients with acute follicular tonsillitis were treated with 300,000 units of procaine penicillin in oil per day for five days Pain on swallowing and soreness subsided rapidly and the exudate promptly disappeared A beta hemolytic streptococcus was isolated from the throat of one patient before treatment was started and was not found thereafter

In the patient with typhoid fever the bacteriologic diagnosis was made on the fourth hospital day After several days during which time there was no improvement on other therapy it was decided to institute a routine similar to that used by Comerford and co workers¹⁵ in the treatment of typhoid carriers Six grams of sulfathiazole were given initially followed by 1 Gm every four hours In addition 300 000 units of procaine penicillin in oil were given every six hours The strain of typhoid bacillus which was recovered from the blood cultures was found to be resistant to more than 20 units per cubic centimeter of penicillin whereas the blood penicillin concentrations prior to injection at the twelfth hour were found to be between 1 and 2 units per cubic centimeter of serum There was no improvement after five days and therapy was discontinued This patient developed an abscess on the buttock from which the typhoid organism was recovered The source of this local infection was not established although it is possible that the bacteria were carried in from the skin by the needles during injections of procaine penicillin This patient later recovered on symptomatic treatment

We have treated fifty seven patients with acute gonorrhea using a single injection of 300 000 units of procaine penicillin in oil plus aluminum monostearate The patients were followed for a period of twenty one days All the patients recovered except one who suffered a possible relapse during the third posttreatment week It is believed however that this patient was re-exposed during the interim

Another advantage of procaine penicillin preparations is the paucity of local reactions. Beeswax, which acts as a foreign substance and which may be antigenic, has been eliminated. We have not been able to demonstrate any sensitivity to procaine penicillin.

The maintenance of continued blood concentrations makes procaine penicillin in oil more desirable in the treatment of infections requiring short courses and more feasible in the cases requiring long courses. The results in the patients treated have been good. The only patients in whom no improvement followed the administration of procaine penicillin were the patient with typhoid fever and the one with acute gonorrhea who probably had a reinfection.

SUMMARY AND CONCLUSION

A new penicillin salt, procaine penicillin, incorporated in oil in oil and aluminum monostearate and with sodium carboxymethylcellulose in an aqueous solution has been studied.

The concentrations of penicillin in the blood at various intervals have been determined following intramuscular injections. The results are expressed both as percentage of patients having assayable levels and as the median levels at the various intervals tested.

Minimal local reactions and no systemic reactions were observed even though twenty nine patients received a second course.

Therapeutic results in patients with various infections were similar to those obtained with penicillin in other dosage forms.

It is concluded that procaine penicillin is a superior preparation for repository penicillin therapy since it does not require the use of dry syringes and needles, is followed by very few local reactions and results in more prolonged blood penicillin concentrations than any penicillin preparation yet studied.

We wish to thank Dr. Mark H. Lopper, Dr. Robert L. Brickhouse, and Dr. Thomas E. Stone for clinical assistance, and Mrs. Joan Broyles, Miss Myrtle I. Meyer, Miss Helen Wright, and Miss C. Barbara O. Neil for technical assistance.

ACQUIRED RESISTANCE OF PSITTACOSIS VIRUS TO SULFADIAZINE AND EFFECTS OF CHEMICAL ANTAGONISTS ON SULFONAMIDE ACTIVITY

ORVILLE J. GOLUB, PH.D.*
CAMP DETRICK, FREDERICK, MD.

THE susceptibility of members of the psittacosis lymphogranuloma group of viruses to sulfonamide activity has been shown to vary considerably depending on the virus strain, the drug tested and the host tissue employed.^{1,2} Among the viruses found to be susceptible to sulfadiazine was the 6BC strain of psittacosis virus^{3,6} originally isolated by Dr. K. F. Meyer. It was shown that although chick embryos and mice could be protected from the lethal effect of the infection, active virus could be recovered from the tissues in most instances indicating that growth was not completely inhibited. Jones, Rake and Stearns⁷ isolated lymphogranuloma venereum virus from mice treated with different sulfonamides and retested these strains in other mice maintained on a diet containing either sulfathiazole or sulfadiazine. Four out of eight strains appeared to show an increased resistance to the drug therapy.

It was considered of interest to investigate further the susceptibility of the 6BC strain of psittacosis virus to sulfadiazine to test the effect of para aminobenzoic acid (PABA) and pteroylglutamic acid† (PGA) on sulfonamide activity, and to develop a strain with increased resistance to sulfadiazine.

MATERIALS AND METHODS

The 6BC strain of psittacosis virus was used throughout this study. Yolk sac passages were maintained as 10 per cent suspensions by weight in nutrient broth, frozen and stored in a dry ice chest. From these stock preparations further tenfold dilutions were made in broth as desired, considering the 10 per cent suspension as a 10⁻¹ dilution. Eight to nine day old embryonated eggs from White Leghorn chickens were used for inoculation into the yolk sac. LD₅₀ estimations of virus activity were performed by the single dilution method⁸ in which the average day of death of a group of eggs is used as the basis for the end point. Employing previously determined standard curves for this strain of virus, eggs were candled daily for ten days at twenty-four hour intervals from the time of inoculation. In many instances a delay in the average day of death was the only available criterion of drug effect although if an effective drug was employed in higher concentrations differences could be expressed in terms of per cent of surviving eggs.

Sodium sulfadiazine, sulfathiazole, sulfanilamide, sulfamerazine and para aminobenzoic acid were dissolved to the desired concentration in distilled water and sterilized by filtration through fritted glass filters. Just prior to inoculation the drug solution and the virus suspension in broth, pH 7.4, were mixed in the desired proportions. The pteroylglutamic acid was made up as its sodium salt in distilled water and inoculated into the eggs one-half hour before the virus.

Received for publication June 24, 1948.

*Present address: Bio Science Laboratories Inc., Los Angeles, Calif.

†The pteroylglutamic acid used was a commercial preparation Folvite manufactured by Lederle Laboratories.

RESULTS

Susceptibility of the Normal 6BC Strain of Psittacosis Virus to Sulfadiazine (SD)—Stock seed of 6BC yolk sac virus of known titer in eggs was diluted in broth to 10^{-3} through 10^{-6} . Equal volumes of these virus suspensions were mixed with solutions of sulfadiazine containing 0.5, 0.25, or 0.125 mg per 0.1 ml or with sterile distilled water as controls. Groups of twelve eggs were inoculated with 0.2 ml of these mixtures by the yolk sac route. On the tenth day of the experiment the yolk sacs were harvested from four living eggs of each group receiving 0.5 mg of sulfadiazine. To determine the virus concentration of the membranes at this period, each yolk sac pool was ground with sterile glass beads, diluted with sterile broth to a 10^{-2} dilution, and inoculated into thirty eggs. The results are shown in Table I.

TABLE I. SUSCEPTIBILITY OF THE 6BC STRAIN OF PSITTACOSIS VIRUS TO VARYING CONCENTRATIONS OF SULFADIAZINE

INOCULUM		D/T*	AVERAGE DAY OF DEATH	LD ₅₀ OF VIRUS FROM LIVING EGGS ON TENTH DAY†

*Dead mice per total inoculated

†Pooled yolk sac material from four eggs of groups inoculated with 0.5 mg of sulfadiazine

A decrease in the concentration of the virus inoculum resulted in a more marked effect of the drug. However, even with the most concentrated virus inoculum, 10^{4.5} LD₅₀ doses, a definite delay in death of the embryos was evident with 0.125 mg of sulfadiazine, although the mortality was 100 per cent. The LD₅₀ figures in the last column show that although many embryos were protected by 0.5 mg of sulfadiazine, in each case active virus was recoverable from the yolk sacs in considerable amount.

Antagonistic Action of Para-Aminobenzoic Acid (PABA) and Pteroyl glutamic Acid (PGA)—Para-aminobenzoic acid as a competitive antagonist of sulfonamides is well documented in experiments with bacteria.⁹ Findlay¹⁰ further reported an experiment in which the effect of sulfanilamide on lymphogranuloma venereum virus administered intracerebrally in mice was antagonized considerably by para-aminobenzoic acid in the diet. Subsequently, Secker

Graessle, and Dusenbery¹¹ were unable to confirm Findlay's results and suggested that the mode of action of the sulfonamides on lymphogranuloma venereum virus differed from their action on other susceptible agents.

Pteroylglutamic acid also has been shown to antagonize sulfonamides, but this compound acts probably in a noncompetitive manner and is quantitatively less effective than para aminobenzoic acid.^{12, 13}

Shortly after the completion of our work a report by Morgan¹⁴ appeared in which antagonism of sulfadiazine inhibition of psittacosis virus by para aminobenzoic acid and pteroylglutamic acid was reported. A competitive inhibition by para aminobenzoic acid was indicated whereas pteroylglutamic acid was said to be noncompetitive in action. As little as 0.05 mg of pteroylglutamic acid was reported to be sufficient to antagonize 25 mg of sulfadiazine in eggs infected with 10,000 LD₅₀ doses. Apparently survival or death of the eggs during the ten day observation period was the only criterion considered for antagonism of the sulfadiazine activity. From the tabulated results 0.1 mg of pteroylglutamic acid antagonized (all eggs dead) as much as 50 mg of sulfadiazine. Our results are similar to those of Morgan with para aminobenzoic acid but may differ somewhat in the experiments with pteroylglutamic acid as will be seen from the data presented below.

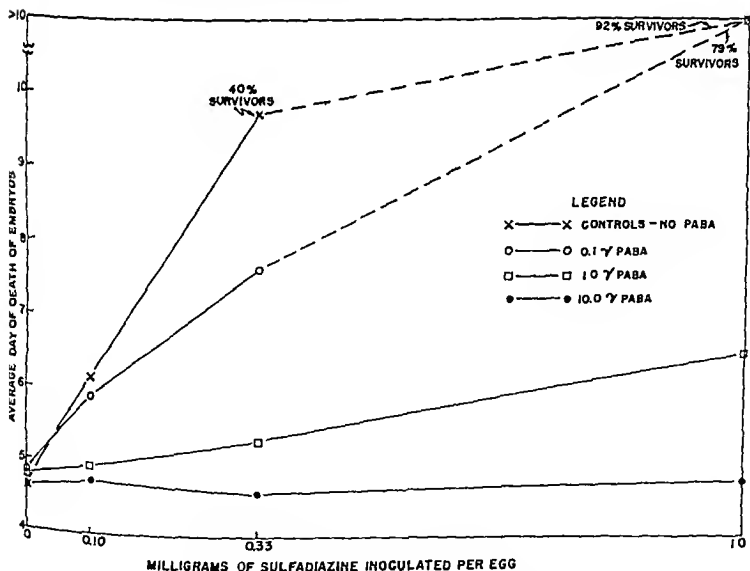

Fig. 1—Antagonism of sulfadiazine by para aminobenzoic acid with psittacosis virus in eggs

Para-aminobenzoic acid was tested quantitatively for its antagonistic activity to sulfadiazine, employing the 6BC strain of psittacosis virus in eggs. The stock virus was diluted to 3×10^{-4} in M/15 phosphate buffer solution at pH 7.5. To aliquots of this virus suspension were added, just before inoculation, equal volumes of sulfadiazine solution (1, 0.33, or 0.1 mg per 0.1 ml) and para-aminobenzoic acid solution (10, 1.0, or 0.1 γ per 0.1 ml). Distilled water was substituted for the chemicals in the control tubes. Each mixture was inoculated into thirty 8-day-old eggs by the yolk sac route, using 0.3 ml per egg. The eggs were candled daily for the usual period of ten days. Fig. 1 shows the results obtained in terms of the average day of death of each group of eggs.

It can be seen by comparison of the values for the average day of death at the different sulfadiazine levels that complete or almost complete antagonism occurred with 10 γ of para-aminobenzoic acid against 1 mg of sulfadiazine and with 1 γ of para-aminobenzoic acid against 0.1 mg of sulfadiazine, which is evidence of competitive action. Even 0.1 γ of para-aminobenzoic acid manifested some antagonistic effect in the presence of 0.33 mg of sulfadiazine, the average day of death was reduced from 9.7 in the control eggs to 7.6 in the test eggs. The relation between the concentration of sulfadiazine and the average day of death appeared to fall in a linear fashion within the ten day observation period.

TABLE II ANTAGONISM BY PTEROYLGLUTAMIC ACID OF SULFADIAZINE ACTIVITY AGAINST PSITTACOSIS VIRUS, 10,000 LD₅₀ DOSE

0.5	None	4.12	25/25	0
0.5	1	4.55	22/22	0
0.5	5	4.43	23/23	0

*Average day of death living eggs not included

Comparable experiments with pteroylglutamic acid as antagonist showed this compound to be less effective than para-aminobenzoic acid. Morgan's results, however, prompted investigation of higher concentrations than first tested by us. Accordingly, 0.1 and 0.5 mg of pteroylglutamic acid, in the form of its sodium salt, were tested against 1 and 5 mg of sulfadiazine in 7 day old eggs as used by Morgan. In order to duplicate conditions, the pteroylglutamic acid and sulfadiazine were inoculated as a mixture in a volume of 0.25 ml, followed by inoculation of approximately 10,000 LD₅₀. Results are shown in Table II in which the average day of death is listed along with the per cent survivors as an indicator of antagonism of the sulfadiazine activity.

It can be seen that 0.5 mg of pteroylglutamic acid antagonized either 1 or 5 mg of sulfadiazine to the extent that all the eggs died and the average day of death (4.43 and 4.55) closely approached the figure for the control group of

that series (412) Since it has been shown⁸ that the growth rate of the virus in the yolk sac is mirrored in the average time of death this measurement is considered to be a more delicate criterion for the degree of antagonism exerted. If virus growth is allowed to continue in a normal fashion the average day of death of the test eggs will be very close to that of the control group and would indicate complete antagonism. With 0.1 mg of pteroylglutamic acid although considerable antagonism is evident against 1 mg of sulfadiazine where only one of twenty six eggs survived the average day of death was 7.00 as compared with 4.03 for the control. Against 5 mg of sulfadiazine approximately half of the inoculated eggs survived and the remainder showed an average day of death of 8.00. These results indicate that the antagonism by pteroylglutamic acid is not complete unless heavy concentrations are employed. When 0.1 mg of pteroylglutamic acid was tested against 50 mg of sulfadiazine eleven out of eighteen eggs survived and the eggs that died had an average day of death of 8.30 compared with 4.23 for the controls. It is possible that free para amino benzoic acid as an impurity in the pteroylglutamic acid preparations may be a factor in the activity shown.

It should be mentioned also that in every instance in which pteroylglutamic acid was inoculated with the virus in the absence of sulfadiazine the average day of death of the eggs was slightly lower than that of the controls. Although the differences were small between 0.1 and 0.5 days they were consistent and suggest a slight stimulating effect of this compound on the growth of the virus.

Since the reports in the literature^{10, 11} concerning the antagonism of para aminobenzoic acid to sulfonamides with lymphogranuloma venereum were contradictory, an attempt was made to test the effect of this antagonist against sulfadiazine using lymphogranuloma venereum virus in embryonated eggs. Stock lymphogranuloma venereum virus of yolk sac origin was diluted to 10^{-2} . Equal volume mixtures of the virus suspension with sulfadiazine solution (0.2 mg per 0.1 ml) and/or para aminobenzoic acid solution (0.01 mg per 0.1 ml) were prepared and inoculated into groups of thirty 8 day old embryonated eggs by the yolk sac route. Distilled water was substituted in the control tubes. The eggs were candled daily for ten days.

Although all the eggs inoculated with the control preparations that is virus alone or virus with para aminobenzoic acid were killed none died of those receiving virus plus sulfadiazine and only two of twenty seven eggs died of those receiving both sulfadiazine and para aminobenzoic acid with the virus. Further duplicate yolk sac pools of living eggs collected from each group on the tenth day of incubation did not indicate any significant differences in virus content between those eggs receiving an inoculum of sulfadiazine alone and those receiving sulfadiazine with para aminobenzoic acid. Thus it is apparent that the para aminobenzoic acid did not antagonize the action of the sulfadiazine as it did when psittacosis virus was employed as the test agent. These results tend to confirm the negative findings of Seeler and co workers¹¹ with this agent with the mouse as test animal.

Development of a Sulfadiazine Resistant Strain of Psittacosis Virus—In order to develop a resistant strain the stock seed of 6BC virus diluted usually

to 10^{-3} , was passed five times by the allantoic route in the presence of 0.5 mg of sulfadiazine. Very few of the eggs thus inoculated died during the ten day observation period, so allantoic fluid from living eggs was harvested for passage on the third to the eighth day. Little or no increase in resistance to the sulfadiazine was noted during this period upon test either by the allantoic or yolk sac route. It was again shown, however, that the allantoic fluid from living eggs inoculated with virus and sulfadiazine harbored active virus, often in considerable concentration, titrating to LD_{50} values as high as 10^{-3} . Yolk sac material was harvested from five eggs, dead on the tenth day, which had received an inoculum of virus from the fifth sulfadiazine passage, plus 0.5 mg of sulfadiazine. This passage virus, 6BC-SD-6, when compared with the parent virus in the presence of 0.5 or 0.25 mg of sulfadiazine, showed some increased resistance as manifested by a reduction in the average day of death. When the daily growth of this passage virus in the yolk sac was compared with that of the parent strain in the presence and absence of 0.5 mg of sulfadiazine, the curve of the 6BC-SD-6 strain lay higher than that of the normal strain in the presence of sulfadiazine, but lower than in its absence. This indicated only partial resistance of this passage virus to the drug. This strain was then passed four more times in a 10^{-2} dilution by the yolk sac route in the presence of 0.5 mg of sulfadiazine, employing yolk sac material harvested from dead eggs on the third to the fifth day. The final harvest, having been passed a total of ten times in the presence of this drug, was labelled 6BC-SD-10.

The LD_{50} titer of this virus in eggs by the yolk sac route was 10^{-8} . The growth curves of this strain were compared with those of a parent stock strain of the same initial titer. Each virus was diluted to a 10^{-3} dilution in broth and mixed with an equal volume of sulfadiazine solution containing 0.5 mg per 0.1 ml of distilled water as a control. Groups of 8-day-old eggs were inoculated by the yolk sac route with 0.2 ml, and at intervals of four hours and of one, three, four, and six days yolk sac pools were harvested from four live eggs of each group as long as they were available. These pools were then each titrated by the single dilution method in twenty-four eggs. The results are shown in Fig. 2.

It is apparent that the growth of the sulfadiazine-resistant strain of virus, 6BC-SD-10, in the presence of 0.5 mg of the drug was practically identical with that of the same strain or the stock strain in the absence of sulfadiazine. All of these eggs were dead by the fifth day. On the other hand, the stock strain in the presence of the sulfadiazine showed definitely slower growth and, among a group of thirty separate eggs of this series, there were 41 per cent survivors at the end of ten days. This strain was further shown to have developed complete resistance to 0.2 mg amounts of sulfathiazole and sulfamerazine. Sulfanilamide, in the same concentration, had no significant effect on the parent strain, so that no difference was detectable with this compound.

Following transfer of the 6BC-SD-10 strain through ten rapid passages by the yolk sac route in eggs in the absence of sulfadiazine, the titer in the yolk sacs reached approximately 10^{-10} . When retested for its activity in the presence of 0.5 mg of sulfadiazine, it was found to have retained complete resistance to

this concentration of the drug. It was then tested against concentrations of sulfadiazine as high as 20 mg. per c.c. and complete resistance was still evident. Since considerable virus of a normal strain is enabled to grow out in the presence of sulfonamides, it is possible that selective breeding plays an important role in the development of a highly resistant progeny by repeated passage.

Fig. —Growth curves of stock strain and resistant strain of psittacosis virus in the presence and absence of sulfadiazine.

An allantoic fluid preparation of the resistant strain was partially purified by several cycles of centrifugation and examined under the electron microscope. No significant differences in morphology were found to distinguish it from similar preparations of the parent virus.

SUMMARY

The 6BC strain of psittacosis virus, although quite susceptible to the action of sulfadiazine in eggs as shown by reduced mortality, multiplied to a considerable extent in the presence of the drug.

Para-aminobenzoic acid was found to be a highly effective antagonist of sulfadiazine with this virus in eggs, and a competitive relationship was suggested. A similar test with the virus of lymphogranuloma venereum did not show any antagonistic effect.

Pteroylglutamic acid was found to require considerably higher concentrations for demonstration of complete antagonism against as little as 1 mg of sulfadiazine, although partial antagonism was demonstrable against 50 mg of sulfadiazine.

By repeated passage of the 6BC virus in the presence of sulfadiazine, a strain was developed which was completely resistant to 20 mg of the drug even after ten passages through normal eggs. Concomitant resistance of this strain to sulfathiazole and sulfamerazine was also demonstrated. No morphologic differences between the resistant strain and the parent virus were observed with the electron microscope.

The author gratefully acknowledges the technical assistance of Miss Vivian Andrew and John C. Young, PhMSc.

THE EFFECT OF NICOTINIC ACID AMIDE ON EXPERIMENTAL TUBERCULOSIS OF WHITE MICE

D MCKENZIE, B S, L MALONE, S KUSHNER, PH D J J OLESON, PH D,
AND Y SUBBAROW, MD PH D
PEARL RIVER, N Y

INTRODUCTION

IN SCREENING some two to three thousand chemicals against the tubercle bacillus on the chorioallantoic membrane of the chick embryo we¹ found that 15 per cent of the compounds were inhibitory. Later all of these active chemicals were screened according to a technique that utilizes white mice. This technique was introduced by two Russian workers, Shpanier and Chertkova² in 1944 and by Youmans and McCarter³ in this country in 1945.

In the Russian report the mice were infected by an intravenous injection of 0.5 mg of a 2 week old culture of the human type of tubercle bacillus, H₃R₁. They were treated with intramuscular injections of the chemical suspended in oil, receiving ten such injections in fifteen days. Evaluation of the results was made by culturing a suspension of the parenchymal organs on egg medium and after one month examining for macroscopic growth of the tubercle bacillus.

In this country Youmans and McCarter³ developed the technique of producing experimental tuberculosis in mice and established a readily reproducible test. Thus they contributed a convenient *in vivo* method of screening a large number of compounds. They injected intravenously 0.1 mg of a TB suspension made from a 3 week old culture. Youmans^{4, 5} used this technique with considerable success in demonstrating the activity of streptomycin and later the activity of *para* amino salicylic acid.

EXPERIMENTAL

Swiss mice* weighing approximately 17 to 20 grams were used in our experiments. These were infected intravenously with 0.25 mg of a TB suspension (H₃R₁) made from a 14 to 18 day old culture. Animals so infected and left untreated usually died in three to three and one half weeks. Though there was no apparent loss of weight in the first one to two weeks, the animals lost weight in the latter stage of infection, and at the time of death they usually weighed 15 to 18 grams. For the most part oral treatment of infected animals was begun on the day after inoculation. The compounds were administered in the diet. The diet consisted of ground Rockland mouse pellets.

Nature of Infection—Though the bacteria were given intravenously, there was no generalized military tuberculosis. Instead the disease seemed to be centered mainly in the lungs the other organs such as the liver, spleen, and

All the chemical substances were included in the diet at the maximum tolerated concentration. The diet was supplemented with nicotinamide in this diet at a concentration of 1 mg. four times daily.

lymph nodes were but slightly involved. The infection in the lungs at the time of death was extensive, varying from discrete white nodular patches to extreme consolidation of whole lobes. Microscopically these nodular patches showed varying stages of consolidation, caseation and monocyte and lymphocytic infiltration to a mere proliferation of tissue. Numerous clumps of acid fast bacilli were observed throughout the tubercles.

Chemotherapy—The apparent tuberculostatic activity of pyridine carboxylic acid on the chorioallantoic membrane of the chick embryo led us to repeat all of the active compounds in infected mice. For the most part these compounds were fed in the diet. Of this group nicotinic acid and its amide seemed to be the most active compounds. Consequently Kushner and co-workers⁹ synthesized a series of thirty derivatives of nicotinamide either in the form of substituents in the acid amide group or as nuclear substitutions. These were tested in mice by the technique already described. The results are given in Table I, but the chemical synthesis and properties of these compounds are published elsewhere.⁹ Nicotinamide was the most active chemical tested. All the changes introduced into the nicotinic acid amide molecule either increased the toxicity or reduced the activity or both.

The failure to increase the activity or even to retain the activity of nicotinic acid amide by any slight alteration in the molecule led us to suspect that we might be dealing with the specific activity of a vitamin. Calculating from our results with mice, on a weight basis the therapeutic dose in human beings would be about 100 to 125 grams—a dose which could not be tolerated by the human subject. So other vitamins were tried at 0.1 per cent concentration in the diet with or without a smaller amount of nicotinic acid amide. Of these only riboflavin seemed to have a slight effect in securing the desired end of reducing the total treatment dose of the nicotinic acid amide. See Table II.

In addition, possible naturally occurring precursors of nicotinic acid amide such as tryptophane and 3-hydroxyanthranilic acid were attempted as chemotherapy, but all yielded negative results.

Resistance of the Tubercle Bacilli to Nicotinic Acid Amide—One of the possible disadvantages of streptomycin in the treatment of human tuberculosis is that the organisms become resistant to streptomycin in the course of time. Similar resistance studies were made in regard to the possibility of the organisms becoming resistant to the nicotinic acid amide. The organisms were recovered from the mouse previously treated with nicotinic acid amide and cultured on egg medium. The bacterial growth was suspended and used for infecting the test mice. Five mouse passages showed little evidence of resistance of the tubercle bacilli but later passages showed some evidence of resistance.

However, when the suspension of the lung excised from the mouse that had been treated with a combination of nicotinic acid amide and streptomycin was placed on egg medium such a sparse growth appeared after a prolonged period of incubation that we believe a very much more reduced number of viable organisms existed in the lungs than when streptomycin was administered alone.

* Streptomycin, 100 mg/kg body weight, daily for 14 days

SUMMARY

The oral administration of 0.5 to 0.75 per cent of nicotinic acid amide in the diet will markedly suppress the spread of tuberculosis in experimentally infected mice.

This amount of nicotinic acid amide in the diet was apparently roughly equivalent in activity to injections of 1 mg of streptomycin four times daily over the same test period.

We wish to express our appreciation to Miss Florence Anderson, Miss Barbara Gosford, Mr Samuel Smith, and Miss Hester Snider for their technical assistance.

PORPHOBILINOGEN TESTS ON A THOUSAND MISCELLANEOUS PATIENTS IN A SEARCH FOR FALSE POSITIVE REACTIONS

ROBERT L HAMMOND, M D,* AND MERRILL L WELCKER, M D †
WORCESTER, MASS

IN THE last decade acute idiopathic porphyria has been accorded increasing attention as evidenced by more frequent clinical reports of the disease, reviews of the subject, and the description⁸ of a new simple diagnostic laboratory procedure. It seemed pertinent to study the Watson and Schwartz porphobilinogen test⁸ which is now widely considered as pathognomonic of this disease. The studies reported in this paper consisted of a search for false positive porphobilinogen tests in a large series of patients.

Briefly, porphyria is defined as a primary idiopathic disease, characterized by abnormal amounts of uro- and coproporphyrins and/or porphobilinogen in the urine, due to a derangement of the metabolism of porphyrin compounds. The term porphyria is opposed to porphyriaemia, which refers to abnormal amounts of coproporphyrins in the urine secondary to a variety of diseases such as lead poisoning, liver disease, or the ingestion of drugs (for instance sulfa drugs, Pyramidon or the salicylates). Porphyria is usually divided into two types: the congenital (or light-sensitive) and the acute idiopathic. Congenital porphyria is the rarest type and is characterized by red porphyrin deposits in the bones and teeth (erythrodontia), photosensitivity of the skin (hydrops aestivale sen vacciniforme), and a dark-red urine. Acute porphyria occurs in adults with intermittent attacks of acute abdominal crises with cramps and constipation, nerve paralysis and mental symptoms, and frequently a dark urine. The porphobilinogen test (see below) is characteristically positive, while in a small series of cases of congenital porphyria, the porphobilinogen test has been negative according to Watson, Schwartz and Hawkinson.⁹

For years the diagnosis of acute porphyria hinged on the large amounts of uro- and coproporphyrin found in the urine. The excretion of the Waldenstrom type of uroporphyrin in particular was shown to be increased in acute idiopathic porphyria.⁵⁻⁹ For a long time the diagnosis of porphyria depended on the chemical identification of uroporphyrin and, to a lesser extent, coproporphyrin, which required a difficult and tedious fractionation. The porphobilinogen test⁸ is a simple procedure useful in the diagnosis of acute idiopathic porphyria.

HISTORY AND PROPERTIES OF PORPHOBILINOGEN AND PORPHOBILIN

In 1931 Sachs⁴ first reported evidence of a substance in the urine of a patient with acute porphyria which gave a red color with Ehrlich's reagent (p-dimethyl-amidobenzaldehyde). She reported that this red compound exhibited two spectral absorption bands with Ehrlich's reagent. The red Ehrlich

From the Departments of Medicine and Pathology of the Worcester City Hospital.

*Intern in Pathology

†Graduate Assistant.

aldehyde compound was insoluble in chloroform differentiating it from the urobilinogen aldehyde compound and as shown later by Watson and Schwartz⁹ from indole aldehyde compound, as formed with Ehrlich's reagent

Waldenstrom and Vahlquist discovered further properties of this substance^{5, 6, 7} They found that if the urine in acute porphyria was exposed to sunlight it became darker and the reaction with Ehrlich's reagent became negative Urea inhibited the development of the reaction Heating the acute porphyria urine with acid caused darkening concomitant with development of a negative Ehrlich's reaction and the appearance of a dark reddish brown pigment which was named porphobilin⁸ Some evidence was elicited by Waldenstrom that this pigment was a dipyrromethene

The colorless chromogen of this pigment was designated by Waldenstrom as porphobilinogen A method for measuring porphobilinogen in arbitrary units has been described⁶ Neither porphobilinogen nor porphobilin has been chemically isolated or structurally identified Prunty has studied the chemical properties of porphobilinogen and has isolated it from the liver in a patient with acute porphyria³ This work indicates that it is not a breakdown product in the urine but is formed in the body probably in the liver Further studies are necessary to evaluate its possible role as a precursor of the porphyrin ring

Watson and Schwartz⁸ provided the first simple clinical test for acute idiopathic porphyria in 1941 and found it to be positive in all of five cases Others have added confirmatory evidence that the test is at least relatively specific^{1, 2, 3}

Watson states¹⁰ that in his laboratories several instances of a false red or pink color have occurred in a porphobilinogen test One was a case of acute polyomyelitis in which the urine contained large amounts of coproporphyrin and urobilinogen In a case of cirrhosis of the liver with large amounts of coproporphyrin in the urine the porphobilinogen reaction was repeatedly although not consistently positive Several urine specimens were found with large amounts of urobilinogen in which it was impossible with repeated extractions to get all of the aldehyde compound into the chloroform The urine from a patient with jaundice showed a positive porphobilinogen test in which the red color behaved like an indicator with variations of pH the red color disappearing with alkalinization In this instance the red color was thought to be due to an extrinsic pigment perhaps a drug Clayons and beets ingested by infants gave weak but definitely positive porphobilinogen reactions Watson now considers the test "in the main very helpful and reliable for porphyria but I do not believe the test can be spoken of as absolutely specific or pathognomonic"

METHODS AND MATERIALS

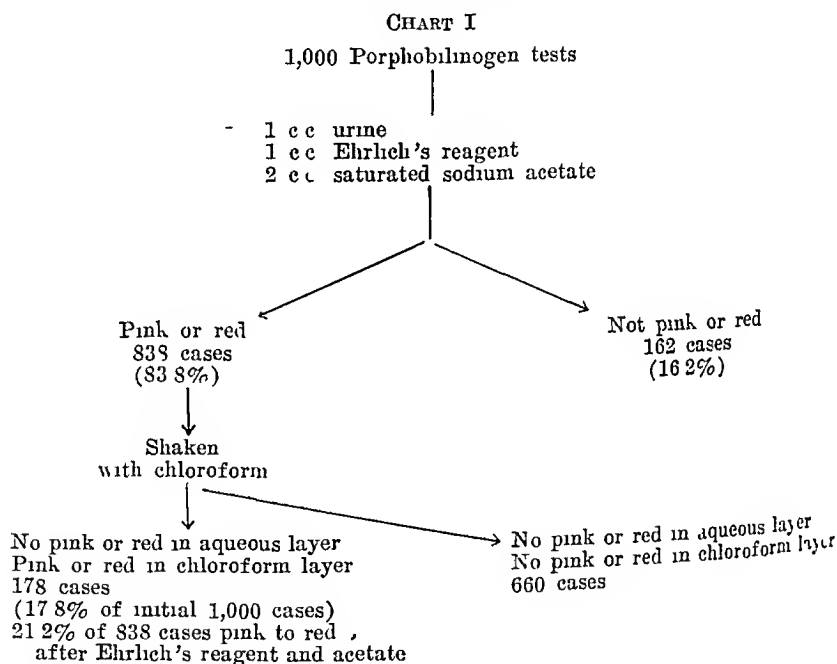

The purpose of the present study was to evaluate this simple office procedure in regard to false reactions There is no conclusive method for ruling out false positive reactions with any simple test except by means of large scale examination of patients with miscellaneous diseases The tests were done in the early morning with fresh urine and from ten to thirty five were done each day Urine specimens of 1000 different patients were examined by the porphobilinogen test of Watson and Schwartz in which 1 ml. of Ehrlich's reagent (0.7 Cm

p-dimethyl-amidobenzaldehyde, 150 ml concentrated HCl, and 100 ml distilled water) was mixed with 1 ml of urine, and then 2 ml of a saturated aqueous solution of chemically pure sodium acetate also were added and mixed. If any pinkish or reddish color resulted, a few milliliters of chloroform were added and the whole was forcibly shaken in a stoppered tube.

The 1,000 patients on which the study was based came from the medical, surgical, obstetric, gynecologic, urologic, orthopedic, neurological, eye, ear, nose, and throat services of the Worcester City Hospital.

RESULTS

No positive porphobilinogen tests were obtained. In no case did a pinkish or red color remain in the aqueous layer when the test was performed properly. It is important to call attention to three points in particular: (1) The chloroform extraction requires a very thorough shaking with the aqueous fraction. (2) Red-colored globules of chloroform frequently adhere to the sides of the

tube in the upper portion giving a false color to the aqueous layer. (3) Reflection of the reddish color from the lower (chloroform) layer into the aqueous layer must be discounted. The authors have been consulted by clinicians who were confused by what purported to be a positive porphobilinogen test in which one of the errors mentioned had occurred. The necessity for these precautions is emphasized by the fact that 838 (83.8 per cent) of the 1,000 cases showed some pink color in the aqueous layer prior to the addition of chloroform. In the majority of the 838 cases the color was a faint pink and in these all that remained after the addition of chloroform was a yellow or slightly orange tint in the chloroform layer. In 21 per cent of the 838 cases the chloroform layer became pink or red after the extraction procedure. The distribution of the reactions is represented by Chart I.

SUMMARY

The simple porphobilinogen test as described by Watson and Schwartz was studied by the examination of the urine of 1,000 patients

No positive reactions were found. From this it may be concluded that false positive reactions are extremely rare, and that the test has a great deal of significance in the diagnosis of porphyria.

HEPATIC DYSFUNCTION IN INFECTIOUS MONONUCLEOSIS, WITH REVIEW OF THE LITERATURE

RALPH E. PETERSON, M.D.*
MINNEAPOLIS, MINN.

THE following paper is a report of the incidence of hepatic dysfunction in a group of hospitalized patients with infectious mononucleosis, with a review of the literature on the subject of liver involvement in infectious mononucleosis.

REVIEW OF LITERATURE

Pfeiffer,¹ in his original description of the disease called glandular fever, mentioned enlargement of the liver as one of the physical findings. Snapper and co-workers² were the first to describe jaundice as a complication of glandular fever. Downey and McKinlay³ in 1923 were the first observers in this country to describe jaundice in a patient with infectious mononucleosis. Later, in 1930, McKinlay⁴ reported a series of fifty cases with jaundice in 10 per cent. McKay and Wakefield⁵ in 1926 reported one case of infectious mononucleosis with jaundice. Schmidheiny⁶ in 1927 reported on eleven cases, with icterus in four. Mason⁷ in 1928 reported two cases with jaundice and suggested that the jaundice was the result of a hepatitis, rather than the result of pressure of enlarged nodes on the common bile duct as had been suggested by McKay and Wakefield.

Nyfeldt⁸ reported a series of thirty-three cases with hepatomegaly in nine and icterus in four, and in 1934 Stuart and co-workers⁹ reported a series of twenty-eight cases with jaundice in two. Failey¹⁰ reported twelve cases with hepatomegaly in four, clinical jaundice in one, and bilirubinuria in an additional one. DeVries¹¹ reported three cases with clinical jaundice in 1938. Paul,¹ in a review of infectious mononucleosis in 1939, reported an incidence of jaundice in 10 per cent of fifty cases. In a later paper Gardner and Paul¹² reviewed 137 cases at the New Haven Hospital and found jaundice in only five per cent, however, 13 per cent had hepatomegaly.

Svaen-Seljesaeter,¹⁴ Fowler and Tidrick,¹⁵ Bernstein,¹⁶ Gold,¹ Howard Carter,¹⁹ Boger,²⁰ Monat,²¹ Leavell and McNeal,²² and Wising³ each described one case with jaundice. Martin²⁴ reported two cases with jaundice, and Chapman and Chapman²⁵ reported seven cases with mild clinical jaundice.

Ollgaard²⁶ reported a large series of 210 cases with icterus in four. Ottenberg and Spiegegel²⁷ reported sixty-seven cases with jaundice in two, Contratto¹ 196 cases with ten jaundiced, Immeiman,²⁹ 220 cases with three jaundiced, Milne,³⁰ 111 cases with three jaundiced, Read and Helweg,³¹ 300 cases with jaundice in eleven but with forty-seven showing hepatomegaly. Spring²² described the clinical picture in five cases with an elevated icteric index. Press

Ft. Lewis Washington

and co workers³³ reported on a series of ninety six cases with jaundice as the presenting complaint in five, though the liver was enlarged in twenty six of the patients

Recently Abrams³⁴ reported one case with jaundice of eleven weeks duration He also mentions an incidence of jaundice of 9.4 per cent in a series of sixty four cases

Halegow and associates³⁵ in a report of an epidemic of infectious mononucleosis in a hospital in England found no clinical jaundice in 296 cases However, only 125 of the patients had clinical symptoms whereas the other 169 had only blood and/or serologic changes They studied fifteen of the more severe cases selected at random and found latent jaundice as manifested by a slightly elevated serum bilirubin, in eight

In a recent report of an epidemic extending over a fifteen month period at an Army post, Wechsler and Rosenblum³⁶ in the largest series of cases of infectious mononucleosis ever reported (556 cases) found thirty five cases (7.0 per cent) with jaundice Most of the cases were mild as far as the icteric index and gastrointestinal symptoms were concerned They found that the liver was palpable in ninety five of the 556 cases however they did liver function tests only in those that showed clinical jaundice Liver function tests in many of these patients showed an elevated direct reacting bilirubin positive cephalin cholesterol test elevated serum alkaline phosphatase increased bromsulfalein retention, and elevated urine urobilinogen In none of the patients that showed jaundice were there any sequelae

Cohn and Lidman³ reported on a group of fifteen successive patients hospitalized at an Army hospital for infectious mononucleosis None of the fifteen were jaundiced clinically however by means of serial hepatic function studies they were able to demonstrate evidence of hepatic dysfunction in all fifteen DeMarsh and Alt³⁸ reported nineteen consecutive cases of infectious mononucleosis without jaundice (icteric index less than 10) of which all showed either positive cephalin cholesterol delayed bromsulfalein excretion or reversal of the albumin globulin ratio Gall³⁹ did liver function tests on thirty three cases serially and found an elevated alkaline phosphatase in all but five cases twenty two of twenty six had positive cephalin cholesterol tests fourteen of fifteen had an elevated thymol turbidity and nine of twenty showed an elevated icteric index (above 8 units) Evans⁴⁰ did liver function tests on nineteen consecutive cases without jaundice (thirteen hospitalized and six ambulatory) He found the thymol turbidity elevated in 68 per cent cephalin cholesterol positive in 95 per cent, alkaline phosphatase increased in 43 per cent and in three cases in which electrophoretic determinations were done on the serum he found an increased amount of beta and gamma globulin

Shry and associates⁴¹ found an elevated thymol turbidity and positive cephalin cholesterol and serum colloidal gold tests in some cases of infectious mononucleosis Carter and MacLagan⁴² found a positive colloidal gold reaction in 9.1 per cent and an elevated thymol turbidity in 58 per cent of nineteen patients with infectious mononucleosis but did not feel that this necessarily indicated any hepatic disturbance

Kilham and Steigman⁴³ were the first observers to demonstrate, by direct observation of the liver cells, that the jaundice in patients with infectious mononucleosis was the result of a hepatitis. In their series of twenty patients there were four clinically jaundiced, whereas others had slight hyperbilirubinemia as demonstrated by laboratory tests. A liver biopsy of one of the jaundiced patients showed a well-marked focal hepatitis. They found maximal changes in the portal tracts with loss of liver cells and a well-developed histiocytic reaction with some early proliferation of bile ducts. The sinusoids showed an excess of Kupffer cells and monocytes. They found no evidence of fibrosis. Van Beek and Haex⁴⁴ did liver biopsies on a patient with infectious mononucleosis without jaundice and described the changes as similar to those seen in patients with myeloid leucemia with many monocytoïd cells and neutrophils. A few of the cells showed mitosis. They did a repeat biopsy on the same patient three weeks after recovery and found the liver to be entirely normal. Bang and Wanscher⁴⁵ did aspiration biopsy on four patients with infectious mononucleosis with jaundice, however, only two of the four had enlarged livers. All of the sections showed pronounced infiltration of the portal areas with lymphocytes, and a few plasma cells, neutrophils, and eosinophils. A few of the liver cells showed mitosis, though no necrosis was evident. There was no evidence of bile duct proliferation or fibrosis. It was their impression that the changes were very similar to those seen in acute epidemic hepatitis with, however, less pronounced parenchymatous changes and more interstitial changes.

Ziegler,⁴⁶ Davis and co-workers,⁴⁷ Fisher,⁴⁸ Allen and Kellner,⁴⁹ and Peters and associates⁵⁰ reported on the histologic picture of the liver of patients with infectious mononucleosis without jaundice or hepatomegaly who were dying of some other cause. The patients of the first three observers had all died of spontaneous rupture of the spleen. In these cases numerous small foci of infiltrations of mononuclear cells were found. Within these foci there was some degeneration of parenchymal cells. Allen and Kellner's patient had been killed in an airplane accident about a week following recovery from infectious mononucleosis. They, also, found many focal areas of infiltrations of mononuclear cells, which were mostly perlobular in distribution. Some of the liver cells showed mitosis. Peters' two patients died as a result of complicating Guillain-Barré's disease. They describe the liver of one of these patients as showing the picture of a moderate hepatitis.

MATERIALS AND METHODS

The present series consisted of forty consecutive patients with infectious mononucleosis admitted to the Students' Health Service* over a fifteen month period of time in 1940-1941. This does not include patients with infectious mononucleosis of a mild nature that were cared for on an outpatient basis. Also, no patients were included in this group whose clinical criteria and laboratory tests were unequivocal for infectious mononucleosis. Patients at some time during the illness had an absolute lymphocytosis with atypical leucocytoïd lymphocytes and a heterophile titer of 1:128 or higher. Of course it is recognized that a small percentage of patients never develop a positive heterophile titer.

*At the University of Minnesota Hospitals

Heterophile determinations were done according to the method of Davidsohn.¹ A titre of 1:112 was considered as definitely positive. Determination of the prompt direct one minute and total bilirubin was made by means of the Ducci and Watson² modification of the Malloy and Evelyn³ method. Values of greater than 0.2 mg per 100 cc of serum for the prompt one minute direct and values of greater than 0.8 mg per cent for the total delayed direct and indirect reacting bilirubin were considered elevated. The thymol turbidity test was performed according to the technique recommended by MacLagan.⁴ Values greater than 4 units were considered elevated. The thymol flocculation was done according to the technique of Neefe.⁵ Values greater than 1+ were considered abnormal. The cephalin cholesterol flocculation test was performed according to the method of Hanger,⁶ and values greater than 1+ at twenty four hours were considered abnormal. The bromsulfalein test was performed according to the method described by Gaebler,⁷ using 5 mg of the dye per kilogram of body weight. The presence of more than five per cent of the dye remaining after forty five minutes was considered abnormal. The alkaline phosphatase was done according to the method of Bodansky⁸ as modified by Alessandri and Ducci.⁹ Values greater than 40 Bodansky units were considered elevated. Total cholesterol and cholesterol esters were determined according to the method of Sperry and Schoenheimer.¹⁰ A total cholesterol greater than 220 mg per 100 cc of serum and/or a depression of the esters to less than 60 per cent of the total was considered abnormal. The estimation of the urinary Ehrlich reaction was made according to the methods of Watson and co-workers.^{11, 12} Ehrlich units of greater than 1.4 per two to four hour specimen were considered abnormal and excretion of more than 3.5 mg of urobilinogen per day was considered abnormal. The urinary coproporphyrin was determined according to the method of Schwartz and associates,¹³ and the excretion of more than 100 gamma per day was deemed abnormal.

RESULTS

Of the forty patients with unequivocal evidence of infectious mononucleosis included in the present study, twenty one (Cases 1 to 21, Table I) showed clear cut signs of hepatic functional impairment as evidenced by three or more positive liver function tests exclusive of the test for urinary coproporphyrin. A few of the remaining nineteen patients (Cases 22 to 40, Table I) showed questionable evidence of hepatic dysfunction on the basis of one or two mildly positive tests. The frequency of the abnormality of the various tests in the forty cases is shown in Fig. 1.

Only one of the patients with hepatic functional impairment had definite jaundice, and only four of the twenty one had an enlarged liver. In three of these four it was definitely tender, and there was tenderness in the liver region in one other patient of this group in whom it was not possible to feel the liver. Forty-eight per cent of the group with hepatic functional impairment had splenomegaly which is about the same (53 per cent) as the group without hepatic dysfunction. All of the patients without laboratory evidence of hepatic dysfunction had a definite pharyngitis whereas three of the twenty one patients with marked hepatic dysfunction had no pharyngitis at any time and three additional patients only developed pharyngitis late in the course of the disease when the hepatitis had nearly subsided. The febrile course did not appear to be greatly different in those with or without hepatic dysfunction. The average maximum temperature elevation in the group with hepatitis was 101.7 degrees F and in the other group, 101.5 degrees F.

Case 22 is of interest in that the patient returned about one week after discharge from the hospital with a complaint of recurrence of malaise, and

Developed pharyngitis late in course of disease after subsidence of hepatitis

rexia, and nausea Examination showed the liver edge to be palpable at the costal margin and moderately tender This picture, along with the elevated thymol turbidity and the positive thymol flocculation test, may have indicated a relapse with a hepatitis, however, the patient quickly improved on a regime of restricted activity

Fig. 1—Percentage of liver function tests that were positive in a group of forty patients with infectious mononucleosis. The numbers at the ends of the bars indicate the number of patients on whom each test was performed.

In none of the group of forty patients were there any serious complications. In the group with hepatic dysfunction, the liver function tests showed a return to normal in a short period of time. In general the patients with hepatic dysfunction appeared to have a slightly more severe form of disease.

The patients with obvious hepatic involvement were placed on a high protein, high carbohydrate diet, whereas the others were maintained on a general hospital diet. Otherwise the therapy was purely supportive with bed rest when indicated by the temperature and degree of hepatic dysfunction, except for the use of penicillin in a few patients who appeared to have developed an exudative pharyngitis or tonsillitis as a complication.

DISCUSSION

For years there has been a debate in the literature about the possible cause of the jaundice in patients with infectious mononucleosis. Most of the early papers mentioning jaundice as a manifestation of infectious mononucleosis suggested that it was the result of pressure of enlarged lymph nodes on the common bile duct, and was thus an obstinate jaundice.^{3, 21, 24, 42} However, "

early as 1928⁷ it was suggested that the jaundice was the result of a hepatitis. With the advent of the use of numerous liver function studies for aids in differentiating obstructive and nonobstructive jaundice it became possible to resolve this question. A number of investigators³⁰⁻⁴⁰ have shown that patients with infectious mononucleosis have the same kind of abnormalities in the liver function tests as patients with epidemic or sporadic infectious hepatitis and homologous serum hepatitis. This work has all pointed to the presence of a hepatocellular and cholangiolar type of liver injury rather than an extrahepatic obstruction as the cause of the jaundice. It also has been found that the general serum protein disturbances are characteristically the same in infectious mononucleosis as those found in infectious hepatitis; that is, a slight decrease in the albumin and a marked increase in the beta and gamma globulins.⁵⁻⁴⁰

The presence of an intrahepatic cause for the jaundice in these patients received more definitive proof with the histologic demonstration of hepatitis as a result of punch biopsies of the liver of patients with infectious mononucleosis with jaundice⁴³⁻⁴ and in a patient without jaundice⁴⁴ and also by the demonstration of hepatitis microscopically in patients with infectious mononucleosis without jaundice on autopsy sections of the liver.⁴⁵⁻⁶

The present study of forty cases of infectious mononucleosis also demonstrates clearly the presence of both hepatocellular and cholangiolar liver damage as the basis for the functional impairment of the liver and in one case (Case 8) for clinical jaundice. Case 16 was of interest in that the patient exhibited predominantly a cholangiolar type of hepatitis; namely, increased prompt reacting (one minute) bilirubin, alkaline phosphatase, total cholesterol and the presence of an intense pruritis.

Thus it would appear that even though jaundice is not especially common in infectious mononucleosis, hepatitis without jaundice is extremely common. The criticism might be ventured, however, that this group of patients is not particularly representative of patients with infectious mononucleosis and that the degree of liver involvement is out of proportion to that seen in the usual hospitalized patient with infectious mononucleosis. Yet the percentage of patients in this series with jaundice (2.5 per cent) is no higher than reported by other investigators: 10,⁴ 12,⁵ 7,⁶ 5,¹² 4,²² 2,²⁶ 3,²⁷ 5,²⁸ 14,²⁹ 7.7,³⁰ 3.3,³¹ and 7.5 per cent.³⁶ The percentage of patients with hepatomegaly might also give some clue as to the probable incidence of hepatic involvement in other reported series. It was 15 per cent in the present group of forty cases. Others have variously reported the incidence at 27,⁵ 33,¹⁰ 13,¹³ 16,³¹ 26,³³ and 17 per cent.³⁰

It is fair to assume that one would anticipate more patients with hepatitis without jaundice than patients with jaundice. It has been demonstrated in the development of experimental hepatitis in human volunteers that the number of patients that develop hepatitis without jaundice exceeds the number that develop jaundice.⁴⁴

The criticism might be anticipated that one could get the degree of hepatic involvement seen in these cases in simple upper respiratory infections or cer-

tain relatively benign viral infections. However, it has been shown by others⁶⁴ that such is not the case, nor have I observed this degree of functional impairment of the liver in the pharyngitides and upper respiratory infections. Also, four of these patients with hepatitis had no pharyngitis at any time and very little fever, and three others did not develop the pharyngitis until after the hepatitis had nearly subsided. For hyperthermia alone to cause a marked degree of liver functional impairment it is necessary for the patient to be exposed to a severe and prolonged hyperthermia.^{65, 66}

A patient with acute infectious mononucleosis and hepatitis and a patient with acute epidemic or sporadic infectious hepatitis often pose a difficult problem in differential diagnosis. Clinically the one symptom that is most valuable in differentiating the two conditions is sore throat. Most all patients with infectious mononucleosis will complain of a moderate to severe sore throat during some period of the illness, whereas this is not a very outstanding sign in infectious hepatitis. As far as physical signs are concerned this is also a valuable guide. There were only four patients out of the entire group of forty that did not have a definite pharyngitis at some stage of illness. All four of these were in the group with definite hepatic dysfunction. This pharyngitis is usually of the nonexudative, nonspecific type, but in some cases is of the exudative type and beta hemolytic streptococci can be isolated from the throat. Lymph node enlargement is distinctly more common and more marked in infectious mononucleosis than in infectious hepatitis, however, the difference is not too striking. Various investigators have listed splenomegaly in infectious hepatitis as 20,⁶⁷ 13,⁶⁸ and 21 per cent.⁶⁸ In our cases of infectious mononucleosis we have found splenomegaly in 48 per cent, which is comparable to what other observers have found: 50,⁴ 47,²⁸ and 34 per cent.³¹

Conversely, the liver is probably much more often enlarged in infectious hepatitis than in infectious mononucleosis. However, Zimmerman and co-workers⁶⁹ found the liver to be enlarged in only 69 per cent of a series of patients with infectious hepatitis in which 90 per cent of the patients were jaundiced. There are few papers on infectious hepatitis without jaundice, so it is difficult to make a comparison with patients with infectious mononucleosis without jaundice. Barker and associates⁶⁴ and Funks and Blumberg⁷⁰ state that in infectious hepatitis without jaundice the liver is usually enlarged. Fifteen per cent or six of the forty patients in this group showed hepatomegaly, and four of these were in the group with hepatitis. Others have reported similar figures: 16 per cent,³¹ and 17 per cent.⁷⁶

Thus it may be seen that there is considerable overlapping in the clinical picture in these two conditions, and in the final analysis one must rely on laboratory tests to differentiate the two. Patients with both infectious hepatitis and infectious mononucleosis show the atypical or leucocytoid lymphocytes of Downey,⁷⁰ Types I, II, and III—mostly Type II. However, patients with infectious mononucleosis have a much greater number and at some stage in the disease practically always have an absolute lymphocytosis with large numbers of leucocytoid lymphocytes, whereas patients with infectious hepatitis only de-

velop a relative lymphocytosis. It has been found that in experimentally induced infectious hepatitis in human beings there is only a relative lymphocytosis with the greatest number of atypical lymphocytes at the fourth to fifth day after the onset of fever.⁷¹ In infectious mononucleosis the lymphocytosis usually is not transient but increases in degree as the disease progresses and usually remains absolute after the symptoms have subsided.

The heterophilic antibody titer is equally as helpful as the lymphocytic reaction in differentiating the two conditions. It is practically always positive in infectious mononucleosis if enough determinations are obtained whereas we have never found it to be positive in infectious hepatitis. Others also have been unable to find an elevated heterophile titer in infectious hepatitis.^{3, 33, 40, 40, 64} Laton and associates⁷² noted a moderate increase in titer of antibodies to sheep red blood cells in some patients with infectious and homologous serum jaundice. These antibodies, however, were of true Forssman type adsorbed by guinea pig kidney, thus unlike those of infectious mononucleosis.

From the present study it is apparent that liver function tests are of little value in differentiating infectious hepatitis from infectious mononucleosis with hepatic functional impairment. The liver profiles of the patients with infectious mononucleosis are for the most part characteristic of those seen in infectious hepatitis. Fig 1 shows graphically the tests that were most frequently positive in the patients with infectious mononucleosis and in general these are the same tests that are positive in the greatest percentage in patients with infectious hepatitis.

The urinary coproporphyrin excretion is increased in both diseases but is of no value in differentiating the two because the increase in both is of the Type I isomer. This is considered in more detail elsewhere.^{3, 74}

In this series of patients with infectious mononucleosis as in patients with infectious hepatitis^{7, 70} the increase of serum bilirubin is due to an increase of the prompt reacting type more than the delayed or indirect. Evans⁴⁰ found the cephalin cholesterol test a more sensitive indicator of hepatic dysfunction than the thymol turbidity test in infectious mononucleosis. In this series the reverse has been found to be true. Also the thymol test remains positive longer than any of the other tests, this also has been found to occur in cases of infectious hepatitis.^{6, 7} In the present series there is likewise shown to be a better agreement between the thymol flocculation and cephalin cholesterol flocculation than between the thymol turbidity and thymol flocculation. This is contrary to what others have found in infectious hepatitis.⁷⁰ It also has been reported as unusual for the thymol turbidity test to be positive in the absence of a positive thymol flocculation test in infectious hepatitis.⁶ However that has not been the case in the present group of cases of infectious mononucleosis.

SUMMARY

A series of forty cases of typical infectious mononucleosis has been studied in which twenty one (55 per cent) of the patients showed moderate to severe hepatic functional involvement or hepatitis as evidenced by a battery of liver

function tests. A number of additional patients in the group exhibited milder hepatic involvement on the basis of one or two positive tests.

It has not been found feasible to differentiate the type of liver involvement in these patients with infectious mononucleosis and hepatic dysfunction from that in cases of acute epidemic or sporadic hepatitis. One must rely on the clinical picture, especially the presence of pharyngitis, the type of lymphocytic reaction, and the titer of the heterophile antibodies. The character of the liver function disturbances in these patients points to the presence of both hepatocellular and cholangiolar liver injury. This evidence together with the histologic findings reported in the literature tends to refute the theory that jaundice in infectious mononucleosis is due to an extrahepatic obstruction of the common bile duct by enlarged lymph nodes.

The literature on the subject of hepatic involvement in infectious mononucleosis is reviewed.

The author wishes to acknowledge the helpful advice and assistance given by Dr C J Watson, and also the technical assistance of Violet Hawkinson and Margaret Griebenham.

FOLIC ACID METABOLISM STUDIES

III INTRAVENOUS ADMINISTRATION OF PTEROYLGLUTAMIC ACID AND PTEROYLTRIGLUTAMIC ACID

B. S. SCHWEIGERT, PH.D.*

COLLEGE STATION, TEXAS

WITH THE TECHNICAL ASSISTANCE OF FRANCES PANZER AND PATRICIA SPARKS

RECENT studies¹ revealed that conjugases present in blood were capable of releasing folic acid from combined forms of the vitamin in blood or from pteroylheptaglutamic acid. This was evidenced by an increase in the folic acid content obtained when blood from various animals including man was incubated at pH 7.0 as compared with the values obtained before incubation.

Considerable interest has developed in determining the comparative effectiveness of folic acid and related compounds in the treatment of macrocytic anemias and related diseases. Excretion studies conducted with normal subjects have shown that negligible amounts (less than 10 μ g per day) are excreted in the urine when average diets are ingested. The urinary excretion of the vitamin is markedly increased however when oral or intravenous supplements of pteroylglutamic acid or its conjugates are administered. The major portion of the dose is excreted in the first twenty-four hours.

The effect of the amount of folic acid ingested on the folic acid content of the tissues, including blood, has been investigated with various animal species.²⁻¹² The apparent free folic acid in the blood of the turkey, for example, is markedly reduced when a diet low in the vitamin is given.^{11, 12}

In the present work the effect of administering folic acid intravenously either as pteroylglutamic acid or as pteroyltriglutamic acid to human subjects on the blood levels of the vitamin was determined at different time intervals after injection. These studies have afforded information on the comparative effectiveness of the two forms of the vitamin in maintaining the blood level and evidence for the rapid cleavage of pteroyltriglutamic acid to compounds active for the test organism *Streptococcus faecalis* R.

EXPERIMENTAL

Normal adult human beings consuming average diets were used in this study. Six subjects were used in each of two series of tests. Three subjects in each series received pteroylglutamic acid and three received pteroyltriglutamic acid. Two of the three subjects in each group also were used in the second series conducted two weeks later and the test compound administered was the reverse of that given in the first series. Blood samples

From the Department of Biochemistry and Nutrition, Agricultural and Mechanical College of Texas.

We are indebted to Dr. T. H. Jukes, Lederle Laboratories, American Cyanamid Company, Pearl River, N. Y., for suggesting this problem and for generous supplies of pteroylglutamic acid and pteroyltriglutamic acid. The cooperation of R. L. Simpson, George Barron, Carl Wilmer, and Sparks Juanita Pou, Dr. R. T. Holman and the staff member of the College Hospital in the course of these studies is greatly appreciated.

Received for publication June 11, 1948.

Present address: Division of Biochemistry and Nutrition, American Meat Institute Foundation, University of Chicago, Chicago 37, Ill.

were taken by vein before injection of the test compound and two, four, eight, and twenty four hours later Pteroylglutamic acid at a level of 12 mg or the equivalent on a molar basis of pteroyltriglutamic acid was injected intravenously

Appropriate dilutions of the ovalated whole blood from each subject at each time interval were made. The blood samples were autoclaved to inactivate the blood conjugases and prepared for assay in the usual manner. The folic acid content was determined after each treatment with *S faecalis* R as the test organism¹⁴. In one of the series, comparative results were obtained when *Lactobacillus casei*¹⁴ was used as the test organism. The amount of folic acid per milliliter of blood is shown graphically in Fig 1 for the *S faecalis* R assays and in Fig 2 for the *L casei* assays. The individual values for each subject obtained at each time interval are also indicated.

Fig 1—Effect of administering pteroylglutamic acid or pteroyltriglutamic acid on the level of folic acid in the blood measured with *S faecalis* R as the test organism. 1, Pteroylglutamic acid (●●), first series (○○) second series. 2, Pteroyltriglutamic acid (●●) first series (○○) second series. The crosshatched circles represent the averages for the six tests conducted at each time interval.

RESULTS AND DISCUSSION

The folic acid of the blood as determined includes only those compounds that have activity for the test organisms without treatment of the sample. Pteroylglutamic acid is equally active for both microorganisms. Pteroyltriglutamic acid is essentially inactive for *S faecalis* R but is quite active for *L casei*.² Therefore in order for pteroyltriglutamic acid to elicit a response with *S faecalis* R, this vitamin derivative must be cleaved to pteroylglutamic acid or other derivatives which can be utilized by *S faecalis* R. For *L casei*, how

ever, both test compounds are active and cleavage of pteroylglutamic acid is not necessary for microbiologic activity. On the other hand if pterone acid is formed it would be essentially inactive for *L. casei* but active for *S. faecalis* R.

It will be noted that the level of the free vitamin in the blood as determined with both test organisms is very low before injection and that it returned to this low level twenty four hours after injection. For many of the subjects the free folic acid level was too low to measure (<0.6 millimicrograms per millimeter). A prompt and rapid rise in the blood levels as determined with

Fig. 2.—Effect of administering pteroylglutamic acid or pteroyltriglutamic acid on the level of folic acid in the blood measured with *L. casei* as the test organism. 1 Pteroylglutamic acid. 2 Pteroyltriglutamic acid. The shaded circles represent the averages for the three tests conducted at each time interval.

S. faecalis R occurred after injection and was at a maximum two hours after injection with a decrease observed in the blood levels four and eight hours after injection (Fig. 1). The data obtained with *L. casei* (Fig. 2) indicate a high level of the vitamin at two and four hours after injection with a rapid fall occurring at eight hours after injection*.

The values obtained for the different subjects at each time interval are in rather good agreement when *S. faecalis* R was used as the test organism with the exception of those obtained two hours after pteroyltriglutamic acid

The data do not permit a definite statement as to the time after injection when the maximum blood levels were reached but are discussed as comparisons at the intervals when analyses were made. The data do show that the maximum blood levels were reached within four hours after the injection of both vitamin derivatives, as measured with *S. faecalis* R.

was injected. The values obtained in the second series appear less reliable since they were calculated from data obtained from the low portion of the standard curve and since they do not indicate clearly a decrease when compared with the data obtained four hours after injection. At any rate, both compounds were effective in raising the blood level of folic acid, and pteroyltri-glutamic acid was utilized essentially as well as pteroylglutamic acid. The over-all response was essentially the same for each subject, and the same was true whether the subject received pteroylglutamic acid in the first or second series of tests.

It is also apparent that conjugases presumably of the blood and possibly from other tissues were highly effective in splitting pteroyltri-glutamic acid into products that were highly active for *S. faecalis* R. The ability of conjugases from human blood to release active components from pteroyl-hepta-glutamate has been described in a previous paper.¹

The values obtained with *L. casei* before injection and twenty-four hours thereafter were in essential agreement with those obtained with *S. faecalis* R. The values obtained four hours after injection were usually higher with *L. casei* as the test organism, particularly when the tri-glutamate was administered, suggesting that some of the injected tri-glutamate was not cleaved for as long as four to eight hours after injection. The over-all curves for the values obtained with the two organisms when either pteroylglutamic acid or pteroyl-tri-glutamic acid was administered correlate very well however (Figs 1 and 2).

It is of interest that an increase in the urinary excretion of folic acid following the ingestion of pteroylglutamic acid or pteroyltri-glutamic acid also occurred only for the first twenty-four hours after administration. These techniques should be valuable for further studies not only on the metabolism of pteroylglutamic acid and related compounds by normal human beings, but also on the metabolism of these important nutrients by patients with diseases that respond to treatment with folic acid and other hematopoietic substances. Since the free folic acid level is very low in the blood of normal human beings receiving normal diets, this measurement alone would not be useful in assessing the nutritional state with respect to folic acid. Additional studies comparing the values obtained with different test organisms for determining folic acid will afford data on the nature of the compounds present in various tissues and body fluids.

SUMMARY

The level of folic acid in the blood of human subjects was determined with *S. faecalis* R and *L. casei* as the test organisms two, four, eight and twenty-four hours after the intravenous administration of 12 mg of pteroyl-glutamic acid or the equivalent of pteroyltri-glutamic acid. A prompt, rapid, and essentially equal rise in the blood levels occurred when these compounds were given. The level was maximum two hours after injection when the first analyses were made, was still elevated eight hours after injection, but was at a normal level twenty-four hours after injection.

The values obtained with *L casei* four hours after injection of the vitamin were somewhat higher than those obtained with *S faecalis* R when pteroyltri glutamic acid was administered indicating that some of the triglutamate was present in the blood for at least four to eight hours after injection. These data also show, however, that conjugases of the tissues were capable of a rapid and effective release of derivatives active for *S faecalis* R from pteroyltri glutamic acid.

STUDIES IN SERUM PROTEINS

IV CLINICAL STUDIES EMPLOYING RAPID CHEMICAL FRACTIONATION PROCEDURES, WITH PARTICULAR REFERENCE TO THE FREQUENCY AND SIGNIFICANCE OF HYPOALBUMINEMIA

W Q WOLFSON, M D, C COHN, M D, E CALVARY, M D,
AND E M THOMAS, M D
CHICAGO, ILL

DETERMINATIONS of "albumin" by salt fractionation procedures have shown this fraction to be decreased in a number of clinical conditions.¹ However, the "albumin" values obtained by such methods are now known to include at least two of the fractions revealed by electrophoretic analysis, namely albumin and alpha globulin. For this reason, and because albumin and alpha globulin have been shown to bear an inverse relationship to each other,^{2,3} a review of the frequency and magnitude of hypoalbuminemia in clinical conditions has appeared desirable.

Electrophoretic investigations have shown a significant decrease in albumin concentration in certain diseases,¹ but because of the limited number of samples which can be handled by an electrophoretic laboratory, the available data do not yet give a true picture of the frequency with which the various conditions responsible for hypoalbuminemia actually occur in clinical practice. Chemical fractionation methods have recently been shown to give results comparable to those obtained by electrophoresis^{2,3} and also to permit analysis of large numbers of samples on a routine basis.⁴ The results to be discussed were obtained by the application of our chemical fractionation method to 500 routine sera.

METHODS

The general principles of the fractionation procedure used are as follows:

- 1 Total protein is estimated with the aid of Weichselbaum's biuret reagent.
- 2 A filtrate containing albumin plus alpha globulin is obtained by treating serum with sodium sulfate at a final concentration of 20.24 per cent. Protein in the filtrate is estimated by the biuret reaction.
- 3 A filtrate containing albumin alone is obtained by treating serum with sodium sulfite at a final concentration of 26.88 per cent. Protein in the filtrate is estimated by the biuret reaction.
- 4 The alpha globulin value is obtained by subtracting the albumin concentration from that of albumin plus alpha globulin.
- 5 Beta globulin plus gamma globulin is calculated by subtracting the albumin plus alpha globulin concentration from the total protein concentration.

From the Department of Biochemistry and the Department of Pediatric Research, Michael Reese Hospital.
These Departments are in part supported by the Michael Reese Research Foundation.
Received for publication May 15, 1948.

6 Gamma globulin is precipitated from serum by ammonium sulfate at a final concentration of 139M at pH 6.0 and controlled ionic strength. The precipitate is dissolved in dilute biuret reagent for the estimation.

7 Beta globulin is calculated by subtracting the concentration of gamma globulin from that of beta plus gamma globulin.

The beta plus gamma globulin component was not further fractionated in this group of patients except in the supplementary group of nephrotic patients presented in Tables IV and V. Complete globulin fractionations are now being performed on a second group of patients and will be reported later.

Detailed working instructions for the rapid estimation of total protein, albumin, total globulin, alpha globulin, beta globulin, and gamma globulin in 10 ml of serum will be published shortly.⁴ The time required to carry through the entire procedure is only slightly more than twice that required for a determination of total protein and albumin by the Howe method.

Fig. 1—Average relation between Howe albumin and serum albumin values in 100 unselected sera.

RESULTS

Comparison of Howe "Albumin" Values With Albumin Values—It is now generally recognized that the 'albumin' values obtained by the Howe sodium sulfate fractionation are always somewhat larger than the albumin values obtained by electrophoresis or by chemical fractionation techniques which have been adjusted to electrophoretic standards.^{2,9*} The difference between the Howe

* For the purposes of clarity we have called the values obtained by the Howe procedure albumin, and those obtained by electrophoretic procedures or by chemical methods adjusted to electrophoretic standard albumin. This does not imply that the albumin fraction isolated by electrophoresis is necessarily a unitary fraction except in its behavior in an electrical field and under suitable precipitation conditions. There is in fact reason to believe that it may consist of at least two major subfractions and several other minor components.

"albumin" values and albumin values has been shown to be approximately equal to the alpha globulin concentration^{2, 7} and to vary with the alpha globulin concentration². In this series of 500 hospital patients, the average serum alpha globulin was 0.84 Gm per cent, with two-thirds of the values within the range of 0.6 to 1.1 Gm per cent. Most of the Howe "albumin" values were therefore from 0.6 to 1.1 Gm per cent greater than the albumin values determined simultaneously. Because this variation in alpha globulin values is not large in comparison with the size of the albumin fraction, the correlation between Howe "albumin" values and albumin values (Fig 1) is approximately linear.

Fig 2—Average relation between albumin and alpha globulin in 500 unselected sera. (Each point represents the average of approximately eighty determinations)

Attempts to apply these data correlating Howe "albumin" values and albumin values to the derivation of a constant correction factor by which albumin may be calculated from Howe "albumin" values meet with certain definite objections, particularly when the accuracy of individual determinations is considered. Although the majority of alpha globulin values in our series fell in the middle range of 0.6 to 1.1 Gm per cent, eight patients had concentrations of 0.2 Gm per cent or less, and sixteen patients had concentrations of 1.5 Gm per cent or greater. Moreover, study of large numbers of samples has shown a definite tendency for alpha globulin concentrations to increase both absolutely and relatively as serum albumin concentrations decrease,^{11, 12, 13} although the scatter of the data both in our series and in that of Chow¹¹ is very large.

Fig 2 shows the average correlation between serum albumin and alpha globulin values which obtains in our patients. At an average serum albumin of 4.81 Gm per cent, the alpha globulin concentration averaged 0.54 Gm per cent, and this value increased to an average of 1.00 Gm per cent at a serum

albumin concentration of 2.76 Gm per cent. Further decreases in albumin concentration did not lead to additional increases in the absolute values of alpha globulin, even though its relative concentration continued to increase. Because those circumstances which lead to a decrease in albumin values also usually lead to increased alpha globulin values the net change in the "Howe albumin," which includes both albumin and alpha globulin will tend to be less than the change in the albumin value.

A more serious defect of the Howe 'albumin' values may be deduced from Fig 1, where the line which represents the relationship between Howe "albumin" values and true albumin values has been extrapolated to the base line. This projection, shown as an interrupted line indicates that at an average true albumin concentration of 0.0 Gm per cent the Howe albumin' value will still be above 1.0 Gm per cent. It suggests that examination of a large series of samples should show the lowest Howe "albumin" values to be about 1.0 Gm per cent. This suggestion appears to have been borne out in our series of 500 determinations. Two patients showed Howe albumin' values between 0.9 and 1.0 Gm per cent, but all others had values of 1.30 Gm per cent or greater. This finding, when considered with the data on the frequency of hypoalbuminemia discussed below, indicates that Howe albumin' values conceal both the frequency and the magnitude of hypoalbuminemia.

Findings in Hypoalbuminemia—In this series hypoalbuminemia has been defined as a serum albumin concentration of 2.0 Gm per cent or less. Such values occurred in fifty samples from thirty-four patients; an incidence of 9.8 per cent. In twenty samples from ten patients (incidence 3.8 per cent) the albumin concentration was 1.0 Gm per cent or less. Howe albumin' values were below 2.0 Gm per cent in only ten patients and 1.0 Gm per cent or less in only two patients.

Electrophoretic studies have shown that marked hypoalbuminemia may occur in severe malnutrition, in the nephrotic syndrome, in chronic tuberculosis, with severe hepatic damage, during relapsing *Plasmodium malarie*^{14, 20} and in the syndrome of idiopathic familial dysproteinemia.^{16, 21, 22*} Examples of each of these disorders, except for the last two, were found during this study, and a few additional diagnoses were noted.

Table I lists the diagnoses made in our cases of hypoalbuminemia and the frequency of each. Quantitatively the largest group was that of patients with the nephrotic syndrome. Two patients in this group had severe renal amyloidosis associated with long standing tuberculosis but the remainder of the patients

Dysproteinemia is a term which has been used to designate an abnormal distribution of the normal plasma protein components and is contrasted with *paraproteinemia* in which abnormal constituents are believed to appear in the plasma as in myelomatosis.⁶ The syndrome of familial idiopathic dysproteinemia has been described by Lionberger, Young, Petermann and Reifenstein²³ as consisting of the familial occurrence of grossly abnormal plasma protein patterns not necessarily with manifest hypoproteinemia. Clinical signs included edema and peripheral circulatory abnormalities in affected women. Armstrong² has referred to a group of similar cases as idiopathic hypoproteinemia and distinguishes two types: one in which the primary disturbance appears to be abnormal plasma protein formation, the other in which increased capillary permeability appears primary. Vuhrmann and co-workers⁴ also distinguish two types: one in which there is hypoproteinemia but with a normal electrophoretic distribution of components, the other in which the electrophoretic distribution resembles that of the nephrotic syndrome (nephrosis sine albuminuria). They have found that both types may be intermittent, edema appearing and diminishing with regular cyclic rises and falls in serum protein values.

were believed to suffer from chronic glomerulonephritis. No attempt was made to differentiate chronic from subacute glomerulonephritis. Three patients were diagnosed clinically as having hepatic cirrhosis. A third group of four patients was classified as having severe gastrointestinal involvement. This noncommittal designation was chosen because it was difficult to assess the relative importance of deficiencies in food intake or absorption and of functional hepatic impairment in the genesis of the hypoalbuminemia.

TABLE I CLINICAL DIAGNOSES IN THIRTY-FOUR PATIENTS PRESENTING SERUM ALBUMIN CONCENTRATIONS OF 2.0 GM PER CENT OR LESS

Nephrotic syndromes	
Nephrotic stage, chronic glomerulonephritis	18
Renal amyloidosis, secondary to tuberculosis	2
Severe hepatic dysfunction	
Hepatic cirrhosis	3
Severe gastrointestinal involvement	
Carcinoma of gastrointestinal tract	2
Intestinal obstruction	1
Following gastric resection	1
Disorders with reticulo-endothelial involvement	
Multiple myeloma	3
Hodgkins' disease	1
Dermatomyositis	1
Rheumatic fever	1
Idiopathic lymphatic atrophy with lymphopenia and hypogammaglobulinemia	1

A final group* of patients were of interest because they presented a variety of conditions in which the reticulo-endothelial system was markedly involved and in which quantitative and qualitative alterations in serum globulins are ordinarily much more pronounced than hypoalbuminemia. This has been true in our study as well, most of our patients with multiple myeloma or rheumatic fever did not show a severe degree of hypoalbuminemia. Although at present the liver is believed to be the sole source of serum albumin,^{23, 24} it is not yet established that the hypoalbuminemia seen in nephrotic patients with mild proteinuria, or in patients with reticulo-endothelial involvement, is to be taken as implying structural liver damage.

Table II lists the average values for the various serum protein fractions found in each of the groups mentioned and for the entire group of patients.

Hypoalbuminemia is most striking in the nephrotic syndrome (Table III). The average serum albumin concentration of the nephrotic patients was only 0.93 Gm per cent, while average serum albumin values exceeded 1.60 Gm per cent in all other groups. *Serum albumin concentrations of 1.0 Gm per cent or less were seen only in the nephrotic syndrome.* Although these concentrations appear small, our data show good agreement with the results of the few reported electrophoretic studies, which are summarized in Table IV.

The absolute values of the alpha globulin and the beta plus gamma globulin fractions of the nephrotic sera was only slightly larger than those of the average hospital patient. Possibly because of the tendency for gamma globulin to be lost in the urine with albumin in nephrosis, gamma globulin values in the

*One patient who presented hypogammaglobulinemia, lymphopenia, lymphatic atrophy, and bronchiectasis will not be discussed in detail in this report. Complete data will be presented in a forthcoming case report.

TABLE II MEAN VALUES FOR SERUM PROTEIN FRACTIONS IN PATIENTS WITH HYGALBUMINEMIA

§ Michael Reese Hospital Serum Center.

patients may be markedly diminished and average gamma globulin values as low as 0.24 Gm per cent have been recorded in electrophoretic analyses.^{18, 20, 21, 28} Gamma globulin levels in amyloidosis however tend to approach normal values,^{18, 20, 27} and a tendency for gamma globulin values to rise during exacerbations of the nephrotic syndrome has been reported.^{20, 27} The relatively normal values of serum gamma globulin in amyloid nephrosis may be associated with the presence of large amounts of gamma globulin in the urine.²

Chemical fractionation values on twenty samples from sixteen nephrotic children are presented in the lower portion of Table III. The average gamma globulin concentration is 0.30 Gm per cent a value in close agreement with the value of 0.33 Gm per cent obtained by averaging the reported electrophoretic data (Table IV). There is a striking correlation of albumin and gamma globulin values. Ten children who had serum albumin concentrations below 1.0 Gm per cent had an average gamma globulin concentration of 0.11 Gm per cent while six children with serum albumin concentrations above 1.0 Gm per cent had an average gamma globulin concentration of 0.62 Gm per cent. This result does not depend upon technical factors in the salting out method since we have shown that serum albumin concentrations do not affect the completeness of gamma globulin recovery by the method employed.⁴ It would appear therefore that whether or not proteinuria is considered to be the sole cause of hypalbuminemia in nephrosis the same factors which are responsible for severe hypalbuminemia are also responsible for severe hypogammaglobulinemia.

As a consequence of the decreased gamma globulin concentrations the beta plus gamma globulin fraction which is roughly equivalent to the Howe globulin comes to consist almost entirely of beta globulin in the average nephrotic

patient (Tables III and IV) The serum beta globulin concentrations show an inverse relationship to the serum albumin concentration The ten children in Table III with serum albumin values below 10 Gm per cent had an average

Total protein concentrations and schlieren patterns appear in the original article.³⁰ The relative concentrations of the various fractions were calculated by Luetscher⁷ from the schlieren patterns. The absolute values quoted in the table were calculated from the data of these two sources with the omission of fibrinogen.

†The study of Malmros and Blax²⁹ was concerned only with patients with elevated sedimentation rates.

¶Etiology chronic tuberculosis.

serum beta globulin of 2.09 Gm per cent, while those with serum albumin concentrations above 1.0 Gm per cent had an average serum beta globulin concentration of 1.36 Gm per cent. With the hyperbetaglobulinemia is associated the hyperlipemia of the typical nephrotic patient since the beta globulin components which are increased in nephrosis carry large proportions of protein bound lipid. The serum cholesterol values in such cases may be greatly elevated, they averaged 799 mg per cent in one series of six patients.³⁰ In such sera the presence of large amounts of lipid makes it difficult to determine the actual concentration of protein in the beta globulin fraction with electrophoretic methods since the lipids transported with the beta globulins increase the size of the beta globulin peak in the schlieren diagram, in this respect chemical fractionation is of distinct advantage, since protein alone is estimated.

Alpha globulin in the nephrotic patients exhibits neither the striking positive correlation with albumin values shown by gamma globulin nor the negative correlation shown by beta globulin. The group of children with albumin concentrations below 1.0 Gm per cent had an average alpha globulin of 1.19 Gm per cent, while those with higher albumin concentrations had an average alpha globulin concentration of 0.99 Gm per cent. These differences are probably not significant, and it seems likely that the failure of alpha globulin values to change significantly may well be due to the fact that its two major components have different physiologic activities. Alpha-1 globulin is a component which resembles albumin in its general behavior and renal clearance and may appear in large amounts in nephrotic urine.³⁴ Alpha-2 globulin, on the other hand more nearly resembles beta globulin in behavior and contains a certain amount of lipoprotein. A simultaneous decrease in the former and increase in the latter might well produce little net change in alpha globulin values.

It is difficult to compare the reported electrophoretic values in nephrotic patients (Table IV) directly with our values. Nineteen of the reported twenty electrophoretic values were obtained on adults while our values were obtained chiefly on children. However in the five adults included in our series of patients with nephrotic nephrosis and in our two cases of amyloid nephrosis, the values obtained by chemical fractionation show less divergence from the mean electrophoretic values than do certain of the individual electrophoretic reports. From our data it appears likely that there may actually be some quantitative differences in the protein patterns of the adult and juvenile nephrotic patient. The average serum albumin is considerably higher in the adults, and from the preceding discussion one might expect this to be accompanied by beta globulin values which are not quite so high as in the juvenile nephrotic subject and by gamma globulins which are somewhat larger than in the younger group. On the whole, the review of electrophoretic data given in Table IV bears out these expectations and supports the view that the information gained by chemical fractionation is not essentially different from that obtained by electrophoretic analysis.

In the groups of patients other than the nephrotic subjects the average albumin values fell between 1.5 and 2.0 Gm per cent (Table II). In the patients with reticulo-endothelial involvement and with hepatic dysfunction, the total

serum globulin and the beta plus gamma globulin concentrations averaged more than 15 Gm per cent greater than those found in the average hospital patient. In the patients with gastrointestinal involvement and in the nephrotic patients total serum globulin and beta plus gamma globulin concentrations either were normal or were increased less than 0.75 Gm per cent.

DISCUSSION

The application of chemical fractionation procedures to a large number of routine hospital determinations has confirmed in general the occurrence of hypoalbuminemia in those syndromes in which this finding previously had been reported by investigators who used electrophoretic analysis. In addition, hypoalbuminemia has been found in certain disorders which involve the reticuloendothelial system and which ordinarily produce more pronounced alterations in serum globulins than in albumin. Statistically cases of the nephrotic syndrome accounted for over half of the patients in whom albumin concentrations of 2.0 Gm per cent or less were found and this syndrome accounted for all of the patients in whom albumin concentrations of 1.0 Gm per cent or less were found.

The finding that hypoalbuminemia is not only most frequent but also most severe in the nephrotic syndrome has certain implications for the pathogenesis of nephrotic edema. It is clear for example that whatever factors other than hypoalbuminemia may be involved^{17, 18, 30, 31} hypoalbuminemia must play a larger role in the pathogenesis of nephrotic edema than in the pathogenesis of any other systemic edema. The low albumin concentrations suggest that the serum albumin of the nephrotic patient may come to consist chiefly of an albumin subfraction of large molecular size^{16, 18, 31, 34} and the absence of compensatory hyperglobulinemia appears satisfactory to account for the greatly diminished plasma oncotic pressure of the nephrotic patient^{3, 35}. It seems possible that edema, in the nephrotic subject increases tissue turgor to a point where increased resistance to loss of fluid from the capillary balances to some extent the increased tendency to lose fluid which is the consequence of hypoalbuminemia. In this way, nephrotic edema becomes a dynamic factor which makes possible the maintenance of a more or less adequate circulating plasma volume. It is not clear why in the nephrotic patient dynamic compensation for

TABLE V. SERUM PROTEIN FRACTIONATION PATTERNS IN PATIENTS WITH HYPOALBUMINEMIA

FOUND IN	NEPHROTIC SYNDROME GASTROINTESTINAL INVOLVEMENT	HEPATIC DYSFUNCTION RETICULO-ENDOTHELIAL SYSTEM INVOLVEMENT	HYPOGAMMA GLOBULINEMIA WITH LYMPHATIC ATROPHY
Total protein	Usually low	Normal or high	Low
Albumin	In nephrotic patients may be below 1.0 Gm %	Above 1.0 Gm %	Above 1.0 Gm %
Total globulin	Normal or elevated less than 1.0 Gm %	Elevated more than 1.0 Gm %	Low
Alpha globulin	Normal or slightly elevated	Usually normal	Normal
Beta plus gamma globulin	Normal or elevated less than 1.0 Gm %	Elevated more than 1.0 Gm %	Very low
V/G ratio	Usually below 0.5	Usually below 0.5	High

decreased plasma oncotic pressure should depend largely upon alterations in interstitial pressure, while in most cases "compensatory" hyperglobulinemia (relative or absolute) aids in compensating for decreased oncotic pressure.

In patients with hypoalbuminemia, the presence or absence of "compensatory" hyperglobulinemia, the severity of the hypoalbuminemia, and the alterations in beta plus gamma globulin concentration make possible a rough differentiation of three patterns of hypoalbuminemia (Table V). In the nephrotic subject and in patients with gastrointestinal involvement, the pattern is that of hypoalbuminemia with little "compensatory" hyperglobulinemia. In patients with hepatic dysfunction and with reticulo-endothelial involvement, albumin concentrations are not so low as in nephrosis, and globulin concentrations are significantly elevated. The pathologic physiology of these latter two groups of diseases strongly suggests that the hyperglobulinemia is in fact not "compensatory" but an effect produced by involvement of the globulin-forming tissue in the disease process. It is possible that the differences in pathologic physiology which are reflected in the findings of Table V may, on occasion, be employed as an aid to differential diagnosis.

CONCLUSIONS

Rapid chemical fractionation procedures which give results approximating those of electrophoresis have been applied to a study of 500 sera received for routine analysis.

Systematic comparison of the albumin values obtained by this method with Howe "albumin" values shows the latter to conceal both the frequency and magnitude of hypoalbuminemia.

Serum albumin concentrations of 1.0 Gm per cent or less occurred only in ten patients with the nephrotic syndrome.

Serum albumin concentrations of 2.0 Gm per cent or less occurred in an additional ten nephrotic patients and in fourteen other patients who were grouped into the general categories: severe gastrointestinal involvement, hepatic dysfunction, and diseases with involvement of the reticulo-endothelial system.

The increase in serum beta globulin and decrease in serum gamma globulin which has been reported in nephrotic adults has been confirmed in a group of sixteen nephrotic children. There is a marked correlation between the degree of hypoalbuminemia, the magnitude of increase in serum beta globulin, and the magnitude of decrease in serum gamma globulin.

Increases in total globulin or in alpha globulin were slight or absent in the patients with nephrotic syndrome or gastrointestinal involvement. In patients with severe hepatic dysfunction or reticulo-endothelial involvement, total globulin and beta plus gamma globulin were increased, on the average, more than 1.5 Gm per cent.

We wish to thank Dr. B. M. Kagan, Director of the Department of Pediatric Research, Medical Research Institute, Michael Reese Hospital, and Dr. R. Sternheimer and Dr. I. I. Ritter of the Renal Service, Division of Medicine, Michael Reese Hospital, for their wholehearted cooperation in obtaining clinical data on certain of the patients reported.

FAILURE OF ANTIRETICULAR CYTOTOXIC SERUM IN ARTHRITIS

DAVID H. KLING, M.D.
LOS ANGELES, CALIF.

THE imposing list of diseases claimed by Bogomolets¹ and his co-workers to have been benefited by the antireticular cytotoxic serum (ACS) includes also acute rheumatism. It is to be regretted that the translators were not aware that in part of the European literature this term indicates rheumatic fever. That the latter was meant by the Russian authors is evident by the qualification that antireticular cytotoxic serum is contraindicated in patients who suffer from endocarditis and myocarditis.

The sensational press notices omitted the word acute and both the public and physicians were fired with the expectation that a cure for all forms of rheumatism was discovered. A great clamor was raised and when the serum was produced in this country it was immediately introduced into the therapy of various forms of arthritis.

Previous studies of the reticulo-endothelial elements in the synovial membrane and its role in the chemotherapy of rheumatoid arthritis^{2,4} have made me aware of objections to the extended concept of the reticulo-endothelial system (RES) and the therapeutic application proposed by Bogomolets and his school. However, for one engaged in the practice of rheumatology, an investigation of the effect of antireticular cytotoxic serum in rheumatic conditions became necessary in order to reach independent conclusions concerning its efficacy.

PREPARATION AND DOSAGE OF ANTIRETICULAR CYTOTOXIC SERUM

The methods of preparation and standardization of antireticular cytotoxic serum were described by Marechuk⁵ and modifications by American investigators⁶ followed.

The majority of our patients received rabbit antireticular cytotoxic serum prepared in lyophilized form and supplied in a combination package. One vial contained 4 ml. desiccated serum and another vial 4 ml. of physiologic saline solution. In order to discover hypersensitivity, a preliminary intradermal test was carried out with normal rabbit serum. Some patients were given rabbit and/or goat antireticular cytotoxic serum.⁷

Two schedules were used. One followed the original directions of Bogomolets. A course consisted of an injection of 0.5 ml. of antireticular cytotoxic serum followed after an interval of two or three days by 1 ml. and concluded with 15 ml. after the same interval.

The second method of administration was developed by Straus and associates. Injections were given twice weekly starting with 0.2 ml. of antireticular cytotoxic serum. The dosage was increased by 0.2 ml. at each subsequent injection to a maximum of 2 or 2.5 milliliters. This dose was repeated up to six weeks depending on the response of the patient.

From the Arthritis Clinic of the White Memorial Hospital, School of Medicine, College of Medical Evangelists.

Received for publication May 13, 1948.

I wish to express my appreciation to Wyeth Incorporated, Philadelphia, Pa. for the supply of ACS serum and extensive abstracts of Russian literature and to Dr. Reuben Straus for the supply of sera and treatment schedules.

[†]Produced by Dr. Straus in the Department of Pathology and Research, Cedars of Lebanon Hospital, Los Angeles, Calif.

With both methods the series can be given several times after an interval of at least four weeks. Before each series the intradermal test with rabbit serum was repeated in order to discover if hypersensitivity had developed in the interval.

In some of our patients we reduced the initial dose to 0.1 ml in order to avoid reactions. If there were marked reactions to rabbit serum, goat serum was substituted. If this also gave reactions, the treatment was discontinued. According to Bogomolets the use of antirheumatic cytotoxic serum is contraindicated in acute and chronic endocarditis, myocarditis, nephros and nephritis, bronchial asthma, and exudative tuberculosis.

It is recommended that injections be given subcutaneously.* The intravenous route was favored by some Russian authors. They (Kavetskiys) applied various tests to determine the functional state of the reticulo endothelial system and the effect of the antirheumatic cytotoxic serum upon it. Most of these tests are too complicated for clinical use, none is specific. Only the sedimentation tests and the hemogram were carried out on our patients. A decrease in sedimentation rate and an increase in the percentage of monocytes and lymphocytes is supposed to indicate an enhanced function of the reticulo endothelial system.

Table I gives the results in sixty cases of the various types of rheumatic diseases.

TABLE I RESULTS OF ANTIRHEUMATIC CYTOTOXIC SERUM IN SIXTY CASES

TYPE	NUMBER OF CASES	IMPROVED		NOT IMPROVED	WORSE
		MODERATELY	SLIGHTLY		
Rheumatoid arthritis	30	1	4	16	9
Osteoarthritis	20	2	4	12	2
Fibrositis	10	2	1	6	1
Total	60	5	9	34	12
		(8.3%)	(15%)	(56.6%)	(20%)

RHEUMATOID ARTHRITIS

Thirty patients with rheumatoid arthritis received antirheumatic cytotoxic serum. They represented a cross section of the adult form of the disease, as seen in our clinic and private practice. Numerous peripheral joints were affected. Cases of Stumpell-Marie spondylitis and Still's disease (adolescent rheumatoid arthritis) were not included. Twenty patients were women, ten were men. The ages ranged from 23 to 63 years. The average age was 45.3 years. The duration varied from two to twenty years, the average duration was five and one half years. The arthritis was mild in three patients, moderate in thirteen, and severe in fourteen. Twenty-three patients had received previously one or more courses of gold therapy and fourteen of these have had significant objective improvement or remission, lasting from one to five years.

Fourteen patients received one course of the short or long series of antirheumatic cytotoxic serum. Sixteen patients were given from two to six series of injections. In the first group the course was not repeated because of local or generalized adverse reactions. During the period of antirheumatic cytotoxic serum therapy, supporting nutritional, physical, corrective, and analgesic treatment was continued.

The results were evaluated after conclusion of the treatment and at a check up six months to a year later. One patient showed moderate and four slight subjective and objective improvement. The amelioration lasted not more than six weeks after completion of the treatment. Sixteen patients showed no im-

*By Wyeth Incorporated and Dr. Straus

provement and nine became worse. The duration of the disease in the moderately improved patient was thirteen years and varied in the three slightly improved from nine to fifteen years. Among those not improved there were four cases of only two years' duration and four of less than four years' duration. Therefore responses were not better when the disease was of shorter duration or in a less advanced stage.

In a control group of 220 patients who were treated with various nonspecific measures alone, about 15 per cent had marked subjective and objective improvement. In 465 patients with rheumatoid arthritis treated by gold therapy, immediate marked objective improvement was achieved in over 52 per cent. Antireticular cytotoxic serum therefore was far less efficient than gold therapy and even nonspecific measures.

The following is evidence that the poor results with antireticular cytotoxic serum were not due to intractability of the material: twelve patients received gold therapy after antireticular cytotoxic serum had failed; of these seven had at least a moderate objective improvement. Four others were improved with other measures.

The initial sedimentation rate varied from 15 mm to 80 mm after an hour Westergren's method. There was no significant change in the rate after antireticular cytotoxic serum therapy even in the five instances associated with some degree of improvement. In patients who had severe reactions the sedimentation rate rose. No marked shift in the hemogram occurred. The number of injections and the length of treatment did not have a significant influence on the results. Three of the slightly improved patients received one to two series of three injections. On the other hand six of those who got worse received multiple courses with as many as fourteen injections per series.

OSTEO ARTHRITIS

Twenty patients with osteoarthritis were treated. All had typical clinical and roentgenographic evidence of the affection. Fifteen had involvement of the spine either alone or associated with osteoarthritis of the hips, hands, and knees. Heberden's nodes were present in four persons. One patient had involvement of the shoulders. The ages ranged from 42 to 73 years; the average age was 55.8 years. Eighteen patients were women and two were men. This unusual distribution resulted from the prevalence of women among our patients. The duration of presenting symptoms was relatively short, from two weeks to three years. The average duration was one and a half years. The sedimentation rates were normal or only slightly elevated in several cases.

Under antireticular cytotoxic serum therapy only two patients were moderately improved and three slightly, twelve were unimproved and three got worse. One of the moderately improved patients relapsed one month after the treatment. Eleven patients unimproved by antireticular cytotoxic serum were given physical, nutritional, orthopedic, and climatic therapy. Of these three were unimproved, eight had significant improvement. Of those significantly

improved, six remained so at least for a year. These results clearly show antirheumatic cytotoxic serum inferior to nonspecific measures commonly used in osteoarthritis.

FIBROSITIS

Ten patients were treated. The presenting symptoms were pain and stiffness of the various muscle groups, especially on arising and after remaining in one position. They were ameliorated after activity and warming up. The lower back, the shoulders, and the arms were involved. There was tenderness and spasm of the affected muscles. Fibrositic nodules could be palpated in some instances. The roentgenograms showed the joints to be normal. The sedimentation rates were normal or slightly increased. The ages varied from 32 to 50 years, with an average age of 43 years. The duration of the symptoms was from six weeks to five years, average duration, two years. Two patients were moderately improved, one was slightly improved, six were unimproved, and one got worse. One patient with fibrositis of the right forearm, which was moderately improved, had a severe local and systemic reaction, with fever, malaise, and headache. A week after the reaction had subsided the patient had a recurrence and spread of the symptoms to the left forearm and lower back. Granted that this group was more chronic and stubborn than the majority of cases, the results of the antirheumatic cytotoxic serum in fibrositis were disappointing.

REACTIONS

Of the sixty patients, thirty-seven (62 per cent) had reactions, of these, fourteen (38 per cent) were mild, nine (24 per cent) were moderate, and fourteen (38 per cent) were severe. There was no significant difference in the degree of reactions in the various types of rheumatic diseases treated. 56 per cent of patients with rheumatoid arthritis, 70 per cent with osteoarthritis, and 60 per cent with fibrositis had reactions. Severe reactions occurred in 23 per cent with rheumatoid arthritis, 20 per cent with osteoarthritis, and 20 per cent with fibrositis. Mild reactions consisted of inflammation and tenderness of an area of several inches surrounding the point of inoculation. In moderate reactions the inflammation spread over a large part of the arm. In severe reactions it involved the whole arm to the elbow. The skin and subcutis became edematous but there was no suppuration. In one case of rheumatoid arthritis an effusion in the olecranon bursa occurred. The reactions started in six to twenty-four hours after injection. With the severe reactions there were low-grade fever of one to three days' duration, joint pain, malaise, headache, and lymphadenitis. In sixteen patients pruritus and urticaria occurred, in six, these reactions were general. Eczema under the axillae and thighs occurred in a patient with rheumatoid arthritis. In one patient with osteoarthritis, ecchymosis and purpuric spots developed around the puncture points and over the forearm. One patient had marked palpitation during treatment. Three osteoarthritic patients developed angioneurotic edema. In two patients the eyelids and in one the lips were involved for several days to two weeks.

The reactions were nonspecific manifestations of hypersensitivity to foreign proteins and/or allergy.

During and after the course of treatment a definite increase in hypersensitivity to antireticular cytotoxic serum occurred in some allergic patients. This is illustrated by a female patient with rheumatoid arthritis who developed urticaria in the first course after 15 milliliters. A second series was started after six weeks with only 0.1 ml and she developed a local reaction and urticaria after the second injection of only 0.2 milliliters. Previous to antireticular cytotoxic serum administration the patient had a severe urticaria after massive intramuscular doses of penicillin and beeswax in oil.

The majority of reactions occurred with increasing dosages of antireticular cytotoxic serum. When the Bogomolets schedule of three injections was used the patients usually tolerated the first injection of 0.5 ml but reacted to the second (1 ml) or third (15 ml) injection. In the longer series starting with 0.2 ml most of the reactions occurred at the middle or end of the course when the dosage approached 1 or 2 milliliters. Two patients treated elsewhere with long series of injections manifested acute inflammation of the previously normal thumb and wrist joints. Prolonged series of injections with very short intervals were given for one or more years by some physicians. If antireticular cytotoxic serum should have a cumulative effect the prolonged therapy may act similarly to a blocking of the reticulo-endothelial system. In experimental animals Emerson, Ewing, and Thomas⁹ produced severe macrocytic anemia by high dosage of antireticular cytotoxic serum.

DISCUSSION

Bach¹⁰ in 1945 reported forty-eight patients with different types of arthritis treated by antireticular cytotoxic serum. Thirty-five of these had rheumatoid arthritis. Rogoff, Freyberg, Powell and Rice¹¹ in 1947 published results on the treatment with antireticular cytotoxic serum of twenty-nine patients with

TABLE II RESULTS OF ANTIRETICULAR CYTOTOXIC SERUM IN RHEUMATOID ARTHRITIS

AUTHOR	YEAR	NUMBER OF PATIENTS	OBJECTIVE IMPROVEMENT		RELAPSED AFTER WEEKS TO 12 MO
			CASES	PER CENT	
Bach ¹⁰	1945	35	3	9	—
Rogoff and co workers ¹¹	1947	29	3	10	—
Boots and co workers ¹²	1947	34	7	20	2
Kling	1948	30	5	16	5
Total	1945-1948	128	18	14	9 (50%)

rheumatoid arthritis. Eight patients with rheumatoid spondylitis (Strumpell Marie type) were included in this series. Boots, Coss and Rigan¹² in 1947 analyzed results in thirty-four patients with rheumatoid arthritis. These authors concluded that the results of antireticular cytotoxic serum were discouraging or inconclusive.

Table II summarizes their combined results and my own in rheumatoid arthritis. Of 128 patients treated eighteen (14 per cent) had some degree of objective improvement. In the majority this improvement was only moderate or slight. In over 50 per cent relapses occurred after a short period. As

pointed out previously, an equal or better percentage of improvement was obtained by nonspecific measures

Moreover, Rogoff and co-workers¹¹ gave to a control group of fourteen patients with rheumatoid arthritis normal rabbit serum alone. Two patients (14 per cent) showed objective improvement and one had subjective improvement. The results equalled those obtained by antireticular cytotoxic serum. This suggests that any benefit may be due to a nonspecific serum effect rather than to the specific influence of antireticular cytotoxic serum. Bach used antireticular cytotoxic serum prepared in Bogomolets' Institute and sent to England. Stiaus¹² recently pointed to the possibility that this serum was inactivated in transit. He found a loss of antibody titer below significant levels in antireticular cytotoxic sera which he had received from Russia. However, this does not explain the equally poor results of the other authors mentioned who worked with antireticular cytotoxic serum produced in the United States and tested and approved in Dr. Stiaus' laboratory.

CRITICISM OF BOGOMOLETS' CONCEPT OF THE RETICULO-ENDOTHELIAL SYSTEM

Rheumatoid arthritis should be the most likely type of arthritis to respond favorably to antireticular cytotoxic serum, if Bogomolets' concept is true. Although its specific etiology is unknown, inflammatory reactions are present in the synovial tissues, in the subchondral bone marrow, in the lymph nodes, muscles, tendons, perivascular and perineural tissues, in the skin, and in other organs. Some investigators regard the disease as a systemic hypersensitive reaction, especially of the mesenchymal tissues, closely related to rheumatic fever. In the latter, according to Stiazhnesko,¹⁴ antireticular cytotoxic serum is beneficial in the second, hypersensitive, stage. Therefore the failure of antireticular cytotoxic serum in rheumatoid arthritis is very disappointing. It was pointed out that Bogomolets and co-workers are not directly responsible for the use of the antireticular cytotoxic serum in these forms of chronic arthritis.

However, the greatly expanded concept of the reticulo-endothelial system, which, besides the macrophages and histiocytes in different organs and subcutaneous tissues, includes all unformed connective tissue and its derivatives, such as osteoid, cartilagens, and synovial tissue, lends itself to the assumption that a general remedy has been discovered for treatment of every disease which is located in organs of mesodermal origin, for instance all forms of arthritis.

Against such unwarranted generalization it should be stressed that the function of the reticulo-endothelial system, which is established beyond a doubt as phagocytosis, storage and digestion of particulate living or dead matter such as bacteria, cells, fat, and colloidal dyes. The evidence of other important functions, such as antibody formation, is controversial.

MacMasters and Hindack¹⁵ and Ehrlich and Harris¹⁶ demonstrated by a series of ingenious experiments that the antibodies are elaborated within the lymphocytes and also possibly by the plasma cells. Under ordinary conditions these cells do not phagocytose or take up selectively vital dyes. The inclusion

of these cells in the reticulo endothelial system therefore is not justified. Kass¹⁷ proved that the lymphocytes produce the normal gamma globulins and the immune globulins. Pomerat¹⁸ has shown that the globulins are the effective fraction of antireticular cytotoxic serum. The antigen is extracted from four parts of spleen and one part of bone marrow. Therefore it contains a large portion of lymphocyte extract and the potency of antireticular cytotoxic serum as an antibody is at least partly due to the lymphocytic fraction. Jaffe¹⁹ rightly pointed out "It is not clear why the authors who have prepared or used extracts of the spleen identify the substances obtained from this organ with the reticulo endothelium since the spleen is composed not only of reticulo endothelial cells but also of other structures."

Applied to the rheumatic diseases, the objections can be summarized as follows:

First it is not proved that the reticulo endothelial system is depressed in any type of these diseases.

Second, the role of the reticulo endothelial system in pathogenesis and therapy has not been definitely established. In the rheumatic diseases presented in this material and reviewed from the literature the results of antireticular cytotoxic serum have been discouraging.

Third, it is doubtful that antireticular cytotoxic serum is a true antireticular serum.

The consistent efforts of Bogomolets and his school have stimulated valuable research. However, until accurate and practical methods of evaluation of the reticulo endothelial system and its role in a given disease have been elaborated and until a firm basis of action and efficiency of antireticular cytotoxic serum has been established and possible adverse effects have been eliminated, its introduction into general practice, especially in the therapy of rheumatic diseases, should not be encouraged.

SUMMARY AND CONCLUSIONS

The therapeutic effects of antireticular cytotoxic serum were studied in sixty patients with different types of chronic rheumatic diseases. On the basis of our material and a review of the literature it is concluded that there is no indication for antireticular cytotoxic serum in the treatment of osteoarthritis and fibrositis, which are ameliorated as a rule by physical, orthopedic, and drug therapy. In rheumatoid arthritis and Strumpell Marie spondylitis which are so serious and often resistant to treatment, a trial of antireticular cytotoxic serum on the basis of an occasional significant improvement may be justified.

Important objections to the concept of the extended reticulo endothelial system have been pointed out.

THE EFFECT OF SUCCINATE IN MESCALINE HALLUCINATIONS

F. W. SCHUELFER, PH. D.
IOWA CITY, IOWA

INTRODUCTION

INVESTIGATIONS by Quastel and Wheatley^{1, 2} have indicated that the oxidation of succinate is not inhibited by the presence of barbiturates and certain of the narcotic amines as is that of glucose lactate and pyruvate. Following this very suggestive conclusion, Soskin and Taubenhaus³ proposed the use of sodium succinate as an antidote to barbiturate poisoning, in which the succinate would serve as an oxidizable substrate until the barbiturate was eliminated from the body. Other investigators^{4, 5} are divided in opinion as to the antidotal effect of succinate in barbiturate hypnosis. Comparative experiments by De Boer¹⁰ concerning the diuretic effect of succinate and sucrose indicate that the decrease in sleeping time produced by succinate in barbiturate hypnosis may be correlated with the degree of diuresis produced.

Succinate also has been found to be of considerable experimental interest in the treatment of diabetic acidosis¹¹ in protection against poisoning by dithiols,¹² and in the place of salicylates in the treatment of rheumatic fever.¹³

In spite of this new interest, the possibility of using succinate in the treatment of narcotic amine depression has not been investigated. In particular we have become interested in the possible effects of succinate on the very striking visual hallucinations produced by mescaline (3,4,5 trimethoxy β phenyl ethyl amine). Mescaline effects have long held the interest of experimental psychiatrists and pharmacologists through the possible insights they may give into some aspects of the mechanism of hallucinosis. The literature on mescaline is vast with a particular emphasis upon visual effects. Kliver¹⁴ in a comprehensive review outlines the visual effects characterizing the progressive intoxication of human subjects from a single dose of mescaline sulfate. These comprise a set of phenomena which are more or less constant for all individuals and include the development of (1) grating, lattice, network, filigree, honeycomb or chessboard, (2) cobweb, (3) tunnel, funnel, alley, cone or vessel and (4) spiral.

Many other phenomena are on close examination nothing but modifications and transformations of these basic forms. The tendency toward geometrization, is expressed in these form constants is also apparent as the intoxication progresses. The forms are frequently repeated combined or elaborated into ornamental designs and mosaics of various kinds. The elements constituting these forms such as squares in a chessboard often have boundaries consisting of geometric figures.

These developments are accompanied by an equally vivid development of brilliant colors incorporated into the changing designs. The compounding of

From the Department of Pharmacology, State University of Iowa.
Received for publication May 6 1948

the designs leads to mental images of formed objects—faces, chairs, mountains, groups of people, and so on

In addition to the visual phenomena, certain physiologic effects will be mentioned later in the discussion which may have some bearing on the results of this study. The foregoing general outline regarding the development of visual effects is important for orientation to the chronological order and depth of the effects produced in the following experiments

EXPERIMENTAL

Experimental procedures were carried out in two directions (1) in vitro studies concerning the effect of mescaline sulfate on rat whole brain respiring on glucose, lactate, pyruvate, and succinate, and (2) in vivo studies on normal human subjects. The method followed in the in vitro studies was that of Quastel and Wheatley² and involved manometric measurements on chopped, mixed, whole rat brain tissue in Krebs-Ringer and (M/15) phosphate medium at a pH of 7.4. The mescaline was made up in Krebs-Ringer-phosphate media and neutralized to pH 7.4 before addition to the brain. The brain suspension (100 to 200 mg) was allowed to respire in air in the Warburg flasks in the presence of the drug until the uptake of oxygen had fallen to about 75 per cent of its

TABLE I

SUBSTRATE	OXYGEN UPTAKE* IN MM ³ AT 37° C FOR 0.5 GM RAT BRAIN FOR 2 HR		PER CENT DECREASE DUE TO MESCALINE
	WITHOUT MESCALINE	WITH MESCALINE (0.1%)	
Saline	300	290	3.0
Glucose 0.025%	620	390	59.0
Sodium lactate 0.025%	730	480	52.0
Sodium pyruvate 0.025%	790	450	53.0
Sodium succinate 0.025%	860	852	1.0

*Each uptake expressed in the table is the average result of seven flasks

initial value, at which time the substrate was added. This initial period was usually about two and one-half to three hours. Readings were taken for two hours after substrate addition, and the per cent decrease in oxygen consumption by 0.5 Gm of rat brain due to exposure to mescaline at a final concentration of 0.1 per cent in the presence of glucose, lactate, pyruvate, and succinate was noted. These results are reported in Table I.

Subjects for the in vivo experiments were sophomore medical student volunteers. These individuals were given doses of 150 to 480 mg of mescaline sulfate intramuscularly and the hallucinations were allowed to develop until the designs observed were of great complexity and the colors of vivid and rapidly changing hues. Then sodium succinate (20 per cent in sterile water) was injected to the extent of 3 to 6 Gm intravenously, and the effects of the succinate on the hallucinations were recorded. The actual procedures were carried out in the Psychopathic Hospital, Department of Psychiatry, where all volunteers were

kept under careful observation at least twelve hours following the acute phases of the experiment

The results of these experiments are outlined in time sequence of the effects, the drug being administered intramuscularly (gluteally) in physiologic saline solution. The acute phases of the experiment were carried out in a dimly lighted quiet room with the subject reclining. Subjects were advised to keep their eyes shut and report frequently with prompting if necessary, the progress of the visions and any other symptoms involved during the course of the experiment. The experiments summarized in the following outline consist of (1) three trials illustrating individual sensitivity to mescaline throughout the acute course of mescaline intoxication (Experiments 1 through 3) and (2) four trials illustrating the effect of sodium succinate given intravenously near what appeared to be a peak effect of mescaline vision development (Experiments 4 through 7). Only those subjects showing a relatively high sensitivity as evidenced by profuse visions of great complexity and color were chosen for the succinate administration.

EXPERIMENT 1—20 year old male subject 132 pounds BP 134/74 pulse, 108/min

- 0 10 150 mg mescaline sulfate intramuscularly
- 0 55 First hallucinatory phenomena Black and red horizontal lines in definite sequence
- 2 58 Lattice work of snow crystals
- 3 00 Square building like objects in all colors in one plane
- 3 08 Swarms of little fish like objects
- 3 15 Perfectly drawn black circles on a yellow background
- 3 20 Purple snails with impression of the sky turned upside down
- 3 25 Looking down on a row of tents hung over a line with scraps of colored glass scattered about
- 3 30 Looking up at sky as through apex of a cone Bright waves of color
- 3 33 "All different colored stars"
- 3 35 Little doll like people coming out of a hall in every direction
- 3 40 "Different colored balls in tinsel going crisscross bumping and sticking together"
- 3 42 Increasing hesitancy to answer questions Fancy buildings lacework bricks "Just floating through"
- 3 45 One woman with a dog, man tips hat wind is blowing and woman is gone Smiles hesitates—"Everything tickles me"—"Most of the time I feel I'm just watching but once in a while I'm taking part"
- 4 00 Big smile Towers, not real towers Incey like Eiffel tower "When I see things, I want to keep them but can't"
- 4 10 "I feel big—big like a man with big hands that can break real big things" Negativism is extreme and subject answers questions with great hesitation.
- 4 30 Chicken coop with wire around—multicolored background "I see spots color spots" "You bother me" "I want to be left alone"
- 4 35 Things getting darker "I'm hungry"
- 4 40 Moved to convalescent ward and a meal
- 5 30 Still a few dull colors and simple designs
- 8 30 Almost all effects except a slight intoxicated feeling have passed off Pushing on eyeballs gives some bright colors
- 9 00 The next morning Feels fine Still some slight color intensification upon pushing on eyeballs

EXPERIMENT 2—23 year old male subject, 140 pounds, BP 119/29 pulse 90/min

- 10 0 210 mg mescaline sulfate intramuscularly
- 10 27 Fingers feel cold
- 10 8 A shiny peach colored ball in center of visual field

- 10 34 A lattice work of lines (when pressing on eyeballs)
- 10 45 Slight nausea and dizziness Sees nothing without pressing on eyeballs
- 11 00 Sees color background start to fill the field, but it passes away when he tries to observe it more closely
- 11 08 A dull green pattern which is greatly intensified by pressing on eyeballs
- 11 20 "Feel bulbous" Feels chair and arm to be out of proportion One side of body vastly larger than the other
- 11 30 Some hesitancy in answering questions with a tendency to gesture and shake head in answering rather than talk
- 12 00 No visual effects without pressing eyeballs
- 12 30 Feels room is distorted and hallway is funnel like but no color or design effects
- 2 00 Feels fairly normal

EXPERIMENT 3—25 year old male subject, B P, 128/68, pulse, 88/min

- 1 27 300 mg mescaline sulfate intramuscularly
- 1 40 Slight vertigo
- 1 50 Fullness in head with tingling in lips and around mouth
- 2 00 Legs feel unusually heavy Visual field somewhat "lighter" but no effects except a dull flicker when pressing on eyeballs
- 2 15 An additional 60 mg mescaline sulfate intramuscularly
- 2 40 No effect even when pressing eyes
- 2 50 Still no visual effects
- 4 20 Still no visual effects Pupils dilated somewhat

Succinate Experiments—

EXPERIMENT 4—Same subject as in Experiment 1

- 1 25 220 mg mescaline sulfate intramuscularly
- 1 50 Predominantly white and black line patterns over field changing to subdued green and blue on white Colors alternating quite rapidly
- 1 55 Lacework—white on black with color in the background getting progressively clearer
- 2 00 Small objects, like letters, revolving on lacework background, then little forms of bright red and orange making up a wheel
- 2 10 Many rings and various abstract patterns getting larger and brighter
- 2 30 Now many bright colored, multiple formed objects floating in air
- 2 45 Brilliant scenes of formed objects like arm chairs floating across valleys (5 Gm of sodium succinate injected intravenously, slowly, into arm vein)
There is an almost immediate dulling of color and the formed objects are replaced by simpler patterns which are on a brownish background
- 2 55 A brownish haze with no patterns The subject is now fairly talkative and exclaims about the rapid change
- 3 30 The visual field seems lighter, but no designs or color even upon pressing on eyeballs
- 3 45 Pressing on eyeballs reveals some fretwork of dull brown
- 4 00 The fretwork design with some bright flashes seems more complicated but is clear only when pressing on eyes
From this time on, light colors appear as background and develop with the brown main part of the lined fretwork type These effects gradually pass off by 9 00 P M

EXPERIMENT 5—26 year old male subject, 175 pounds, B P, 120/74, pulse, 90/min

- 1 25 480 mg mescaline sulfate intramuscularly
- 1 35 Six spike snowflakes clustered around a luminous ball of green yellow in the center
- 1 45 Bright yellow circle like a doughnut The background is marked off in horizontal lines
- 2 00 Feels "high," drunk Brilliant colors everywhere Feels very much disoriented in space
- 2 40 Complicated designs and rapidly changing colors The subject is very hesitant at first time in answering questions
(6 Gm of sodium succinate injected intravenously)

- 0 50 "Color and design are gone except for dark blue black background
 3 00 A few dark blue lines on dark background Intoxication is passing off The subject talks freely with no hesitancy Now feels somewhat euphoric
 3 30 Still no color or design but feels a little euphoria again
 4 00 Feels somewhat numb and euphoric with a light color tinged visual field with definite simple dull colored fretwork designs
 7 00 Euphoria has passed off Very sleepy and exhausted

EXPERIMENT 6—22 year old male subject 131 pounds B P, 121/80 pulse 85/min

- 1 43 2.0 mg mescaline sulfate intramuscularly
 1 50 Feels a slight 'hardness' that comes and goes
 2 30 Dull flashes of light with background of green fading to purple
 2 45 A whirling design like a fan with violet spider webs
 2 50 Colors brighter with much red and green and occasional designs in orange or yellow
 2 55 People in silhouettes piling on top of each other on a background of Indian designs
 A bright sun appears and spirals of bright yellow
 3 10 Brilliant patterns with silhouette figures in all colors
 (3.5 Gm of sodium succinate intravenously)
 3 30 Colors have blurred and show mainly dull browns and greens on a black background
 3 35 Visual field is still dull with simple fretwork design on dark background only upon pressing eyeballs
 4 00 Feels fairly normal with color in background only on pressing
 5 00 Color is returning with drunkenness and high feeling Colors quite vivid but patterns simple when pressing eyeballs
 6 00 Still 'high' with some color mostly dull browns and greens or blues in background
 Color brightens when pressing eyeballs
 8 00 All color passed off with only some general visual field green or brown

EXPERIMENT 7—Same subject as in Experiment 5

- 1 45 450 mg mescaline sulfate intramuscularly
 1 50 Gray snowflakes in black and white mosaic pattern
 1 55 'Exhausted like at end of the day'
 2 00 A little aroused
 2 10 Black and gray white background with pin points of yellow and green Color fading
 'in and out'
 3 00 Design is increasing in complexity with light increase in color Fretworks cobweb designs 'melting in and out'
 3 40 Progress in complexity with many details various parts of visual field show isolated
 "independent activity and development with effect of third dimension and perspective
 3 00 A considerable increase in color with many formed objects—people animals in constant movement with a brick colored mosaic background
 3 30 Much beautiful coloration and formed objects in three dimensions
 (5 Gm of sodium succinate intravenously)
 3 35 Faces of people and formed objects rapidly melt and dissolve with an almost immediate cessation of color effects
 4 00 No patterns or color even when pushing on eyeballs Feels fairly normal with a little euphoria
 4 00 Some vague design of a simple mosaic type when pushing on eyeballs
 4 30 Still some simple design and a little color when pushing on eyeballs
 5 30 Feels quite normal but sleepy and hungry
 8 00 Sees vague gray on black, simple lattice work when pushing on eyes in a darkened room

Miscellaneous Effects Observed in Some or All of the Subjects Which Are Caused by Mescaline and Which Are Antidoted Partially by Succinate—Abolition of cremaster reflex, abolition of bladder filling sense, increased knee jerk reflex, depression and decrease in cooperation, with hesitancy of speech, space and time distortion, depression of respiration

Effects Not Antidoted by the Succinate—Dilatation of the pupil, hunger, tightness across the face

DISCUSSION OF RESULTS

The in vitro experiments carried out on rat brain illustrate and confirm in essence the information obtained by Quastel and Wheatley that oxidations by brain tissue are inhibited less by mescaline when respiring on succinate than when utilizing glucose, pyruvate, or lactate. It should be pointed out, however, that these inhibitions are obtained only if the brain is incubated with the drug in the absence of substrate for the initial two and one-half to three hour period. None or very little inhibition was obtained in this laboratory when the substrate was added at the beginning even in the presence of vastly larger quantities of mescaline (up to 0.5 per cent). In light of the fact that relatively small doses of mescaline, considering the total body weight of human subjects, produce profound effects within thirty to sixty minutes after the intramuscular injection, it is difficult to correlate the conclusions of the previous investigators regarding the in vitro effects of mescaline with the rapid, very dramatic effect which it produces in relatively small doses in vivo. Nevertheless, the implication of an antidotal effect by succinate, in greatly decreasing the complexity of designs and color, was strikingly demonstrated. The immediate effect of succinate seems to be the complete cessation of hallucinosis in some instances and in others a decided regression of the visions to an earlier, simpler design with great loss in color intensity.

That the effect of succinate in lessening the hallucinosis can be due to a diuretic effect seems also unlikely since the succinate effect is so immediate. In addition, after thirty to sixty minutes the succinate effect seems to lessen, and color and design again appear, though still much less profuse than before the succinate. This would seem to indicate the presence of still toxic amounts of mescaline, making an antidotal hypothesis based upon a diuretic action seem untenable. Possibly a considerable part of the injected succinate has been utilized by other cells of the body in thirty to sixty minutes.

Also observable was an antidotal effect of succinate with regard to the general demeanor and physiologic responses of the subjects. Thus the decrease in cooperation and hesitancy in speech observed were replaced after succinate by a more normal attitude and readiness to talk. The bladder filling sense returned and there was some lessening of the knee jerk reflex toward the normal. Respiration was increased by succinate, as was observed by others.^{14, 15} Regarding less of the mechanism, the effects seem most striking as described by one subject immediately after injection of succinate, "It was as if the colors and designs were being washed away."

SUMMARY

In vitro and in vivo experiments with mescaline sulfate were carried out. The in vitro experiments confirm the observations previously witnessed regarding

ing the lack of inhibitory action of mescaline on brain respiring on succinate and the definite inhibition of brain respiring on lactate, pyruvate, and glucose. In vivo experiments in human subjects demonstrate an antidotal effect of succinate on mescaline visions with regard to a decrease both in complexity of design and intensity of color. A consideration of the relatively large amounts of mescaline required to suppress brain respiration in vitro as compared with that required for the production of its in vivo effects, however, leaves some question as to the relation of the in vitro suppression to the process of hallucinosis.

The author wishes to acknowledge the assistance and advice of Dr J S Gottlieb in the use of intravenous sodium succinate and the suggestions of Dr E G Gross in the selection and use of subjects in human experimentation.

ABSORPTION, DISTRIBUTION, AND RENAL EXCRETION OF MANDELAMINE (METHENAMINE MANDELATE)

JOHN V SCUDI AND JOHN F REINHARD
YONKERS, N Y

MANDELAMINE, a urinary tract antiseptic now in clinical use, has been the subject of recent investigations in which it was reported^{1,2} that Mandelamine, streptomycin, and sulfathiazole are approximately equal in their activity against organisms which commonly invade the urinary tract. It was found that organisms develop resistance to sulfathiazole and streptomycin rapidly, and to a remarkable degree, but, in contrast with these findings, resistance to Mandelamine did not appear at all. In order to gain further insight into the properties of Mandelamine, the following pharmacologic studies were undertaken.

EXPERIMENTAL

Chemical Methods—Forty cubic centimeters of 0.1N sulfuric acid were added to solutions of Mandelamine (50 to 200 mg per cent) and the solutions were steam distilled at a rate to produce 40 cc of distillate in sixteen minutes. The distillate was analyzed for formaldehyde by means of Deniges' colorimetric method.³ Two hours were required for full color development. Final readings, measured in a photoelectric colorimeter at 5,800 Å units, were compared with a reference curve prepared by using standard solutions of formaldehyde. (One gram of formaldehyde is equivalent to 1.62 Gm of Mandelamine.) The sixteen minute distillation was selected because approximately 50 per cent of the Mandelamine is hydrolyzed to formaldehyde in this conveniently short period of time. Under these conditions analysis of Mandelamine solutions (3.12 to 200 mg per cent) gave an average recovery of 93 per cent (Table I). Results are, therefore, divided by .53.

The method is directly applicable to urine, but application to blood requires a protein free filtrate prepared according to the Haden modification of the Folin Wu procedure. Mandelamine added to whole blood in concentrations of 50 to 200 mg per cent is recovered as shown in Table II. The limit of sensitivity of the method, 0.6 mg per cent, corresponds to a concentration of 6 mg per cent in whole blood. In actual practice more reliable results were obtained when blood concentrations were 20 mg per cent or above.

Creatinine was determined according to the Folin Wu colorimetric procedure⁴ modified for photoelectric measurement at 5,300 Å units.

Distribution of Mandelamine in Whole Blood—Mandelamine (25 to 200 mg per cent) was added to heparinized dog blood and the mixture was shaken gently for thirty minutes. Samples of whole blood and plasma, analyzed for their Mandelamine content, gave the data (expressed in terms of blood and plasma water) shown in Table III. In order to approach physiologic conditions more adequately, the drug was injected intravenously into dogs, and samples of whole blood and plasma were then analyzed as before. The data indicate that the drug readily penetrates the red blood cell and distributes itself in proportion to the water content of whole blood. These experiments are of interest in con-

nection with the following studies of the renal excretion of Mandelamine. It may be noted here that the cellophane membrane has been employed rather than the cellophane membrane frequently used in studies of protein binding.

Renal Clearance and Distribution of Mandelamine in the Dog—Four mongrel, male dogs (weighing 7 to 14 kilograms) maintained on a standard ration were fasted overnight before each experiment. At the onset the dogs were given 300 to 500 cc of water by stomach tube and light anesthesia was induced by intravenous injection of 60 per cent of the anesthetic dose of Nembutal. Creatinine (150 mg per kilogram) was injected subcutaneously and ten minutes later additional creatinine was given both subcutaneously (75 mg per kilogram) and intravenously (75 mg per kilogram). Mandelamine (250 to 750 mg per kilogram) was administered intravenously thirty minutes after the creatinine

$\frac{a \times 100}{b}$ = per cent in (dl./kg) $\times \frac{a-b}{10}$
 a = amount of drug in blood (mg) b = amount of drug in (dl./kg)

Under these conditions an adequate urine flow and a reasonably constant plasma level of creatinine were maintained. In the first three experiments eight urine samples were taken by catheter at measured intervals of approximately fifteen minutes each, and five samples of blood were collected during the test period. In the last two experiments four samples of urine and three samples of blood were collected. The plasma concentrations were plotted against time on semi-logarithmic paper and appropriate plasma concentrations were interpolated from the best straight line in accordance with the procedure described by Newman, Gilman and Phillips. The data were used to calculate clearance ratios and volumes of distribution as shown in Table I.

It is evident from the clearance ratios that Mandelamine undergoes reabsorption in the renal tubules. Closer scrutiny of the clearance data reveals two ratios which were manifestly out of line. These presumably resulted from analytic errors. It may be noted that the first Mandelamine and creatinine clearances were low. No explanation is offered for this observation but it is suggested that the depression in these clearance values may be the result of a temporary hypotension induced by the intravenous administration of the large doses of Mandelamine. No correction is included for possible binding of Mandelamine to plasma protein because the distribution of Mandelamine in whole blood indicates that the drug is freely diffusible. The volumes of distribution are consistent with the view that the drug is freely diffusible and rapidly attains equilibrium in its distribution in the compartments of body water.

The volumes of distribution observed within the first hour approximated the total volume of body water. With increasing time however the volumes of distribution increased to values as high as 87 per cent of the body weight. Because only 45 to 70 per cent of the total dose administered can be recovered in the urine, it is reasonable to assume that the apparent increase in the volume of distribution with time results from metabolism of the drug.

Acute Toxicity of Mandelamine—Jenkins, Jack and Drake,⁶ Kolloff and Nelson and others have reported on the lack of toxicity of Mandelamine. In order to confirm and extend these findings the acute toxicity of Mandelamine was determined in mice (weight 17 to 22 grams male, Carworth Farms (C.F.) No. 1 strain), guinea pigs (weight 300 to 400 grams male), rats (weight 100 to 200 grams C.F. male) and albino rabbits (weight 3 to 4 kilograms male). Buffered solutions of Mandelamine were injected intravenously. In all species, signs of acute toxicity consisted of convulsions, extension of the extremities, respiratory paralysis, and cardiac arrest. The data based on ten to twenty animals per dose point are summarized in Table V. The notable lack of toxicity of Mandelamine is in agreement with work reported earlier.

TABLE V INTRAVENOUS TOXICITY OF MANDELAMINE

SPECIES	LD ₅₀ (mg/kg)	LIMITS OF ERROR (%)
Mouse	3.75	97-104
Guinea pig	1.50	89-112
Rat	>4.0	-
Rabbit	>2.0	-

Buffered solutions of Mandelamine (1.25 to 10 per cent in physiological saline) were injected into the shaved abdominal skin of the rabbit. An irritant drug included to insure a positive response produced severe necrosis at the sites of injection, but the buffer saline and Mandelamine solutions gave uniformly negative results.

Urinary Excretion of Mandelamine in Human Subjects—Clinically 1 Gm. doses of Mandelamine are administered by mouth three or four times daily. One gram of Mandelamine therefore was administered orally to each of five male volunteers* with the results shown in Table VI. It may be seen that effective concentrations¹ of the drug were attained in the urine within three or four hours, indicating a relatively slow absorption, and these concentrations persisted for at least another seven to eight hours. In a second experiment involving four normal male subjects 1 Gm. of the drug was given and after six hours a second dose was administered. Urine samples collected at the times indicated in Table VI were analyzed for their Mandelamine concentrations with the results shown. In a third experiment (undertaken because of the notable lack of toxicity of Mandelamine) twice the recommended dose, namely 2 Gm., was administered to two volunteers and the dose was repeated in twelve hours. As shown in Table VI this dose schedule also gave adequate urinary concentrations around the clock. It may be concluded from these data that 1 Gm. of Mandelamine administered by mouth three or four times daily will in the presence of normal renal function, produce and maintain antibacterial concentrations of Mandelamine in the urine.

TABLE VII. URINE CONCENTRATIONS AFTER 1 Gm. MANDELAMINE THREE TIMES DAILY FOR FOUR DAYS

SUBJECT	DAYS				MEAN VALUES
	1	2	3	4	
J. M.	130.7	101.6	65.5	110.4	102.9
J. F. R.	64.5	71.7	63.4	50.5	62.7

L.	100.9	105.5	104.5	100.9	110.7

In order to establish more convincingly the effectiveness of the accepted dosage nine volunteers were given 1 Gm. of Mandelamine by mouth at 9:00 A.M., 5:00 P.M. and before retiring. These experiments were continued for a period of four consecutive days. It should be emphasized that these subjects continued in their normal occupations with no limitations imposed upon the fluid or food intake. Daily urine samples collected at 10:00 A.M. were analyzed with the results shown in Table VII. All urinary concentrations were within or above the range of antibacterial effectiveness. The mean of all values was 133 = 308. Although the figures varied significantly among themselves it could be shown by analysis of variance that differences within individuals were no significant within the observation period of four days. It may be concluded

*Commercial Mandelamine tablets were used in all human experiment.

therefore, that a dose of 1 Gm three times daily will, in the presence of normal renal function, produce antibacterial concentrations of Mandelamine in the urine

Carroll and Allen⁸ have reported that, following ingestion of Mandelamine, the urine of 96 per cent of their patients became and remained acidic without other medication or restriction of diet or fluid intake. Our findings in normal subjects are in agreement with those of Carroll and Allen. Invariably the urinary pH was lowered, and in all instances a single dose of 1 Gm was sufficient to lower the urinary pH to about 6. The urinary pH was maintained between 5.8 and 6.4 when 1 Gm of the drug was administered three times daily for four days.

SUMMARY

Mandelamine readily penetrates the red blood cell and distributes itself in proportion to the water content of whole blood. In the dog the volume of distribution approximates the total volume of body water. The volume of distribution increases with time, presumably because of extrarenal activity. The drug undergoes tubular reabsorption in the dog. These observations are consonant with the view that the drug persists in the organism. In human subjects, 1 Gm of Mandelamine administered three or four times daily is adequate to produce and maintain antibacterial concentrations of the drug in the urine. The notable lack of toxicity of Mandelamine is confirmed.

LABORATORY METHODS

IMBEDDING OF PATHOLOGIC SPECIMENS IN TRANSPARENT PLASTIC

MAX M. STRUMIA, M.D. AND J. IRAN HERSHEY, M.D.
PHILADELPHIA, PA.

INTRODUCTION

IN THE teaching of biologic sciences it is essential to be able to demonstrate specimens of animals and soft tissues. This is even more true of some of the medical sciences, particularly gross anatomy and pathology. The preservation of such specimens always has presented a very difficult problem. The most usual and probably the most satisfactory method at present in general use consist in fixing the organs or slices of organs in various fluids, most of which as a rule contain formalin, with the addition of various substances designed to retard as much as possible the loss of color and shrinkage. These specimens generally are mounted in round or square glass jars. Even with the greatest care, however, and with the best known procedures, this method offers numerous disadvantages. First of all, color preservation is good to fair for only a relatively short period of time, because on standing there is progressive bleaching. In the second place, shrinkage takes place with distortion of the specimen. Third, there are the factors of weight and difficulty in handling bulky museum jars with the danger of breakage, difficulty of transportation and so on. In addition there is generally great difficulty in perfectly sealing such jars, with the necessity of adding or renewing the fluid from time to time, and finally the preserving fluid becomes discolored and after a period of time needs renewing. Very often also turbidity occurs.

Employing substances generally known as plastics which can be transformed from the liquid to the solid state, successful attempts have been made particularly by Sando,¹ to imbed minerals, insects and similar structures in transparent blocks.* However, the procedure involved the use of chemical dehydrating agents, and it could not be applied successfully to animals or organs of animals containing large amounts of water without considerable loss of form and color. The combination of drying from the frozen state (by sublimation of water vapor) impregnation of the dried tissue with the liquid monomer polymerization and subsequent imbedding in a transparent solid plastic has yielded good preservation of both color and form of the most delicate human, animal and vegetable tissues.

The use of dehydration by sublimation of water from the frozen state was suggested by the fact that plasma and other complex colloidal substances can be dried without deterioration.²

From the Department of Clinical Pathology of the Bryn Mawr Hospital and the John S. Sharpe Research Foundation of the Bryn Mawr Hospital.

This work was aided by a research grant from the Rohm and Haas Company.

Received for publication May 4, 1948.

Very recently Kampmeier and Haviland have published a method for the mounting of wet anatomic preparations in Castolite. This method does not preserve the natural color in specimens.

Thus far the work has been directed toward developing a satisfactory basic technique. Since the time of the publication of a preliminary paper⁴ the method has been considerably improved and applied to imbedding of practically every organ of the human body and numerous other animal and vegetable specimens. The early promises of this method have been at least partly realized. The present publication deals mostly with presentation of the technique which has given the most constant and satisfactory results. This technique suggests itself for application for the collection of anatomic and pathologic specimens for teaching in schools, medical and veterinary, and for the teaching of biology, zoology, botany, and the allied sciences.

PROCEDURE

Material—The material used for imbedding is uninhibited monomer consisting of a mixture of 90 per cent methyl methacrylate and 10 per cent ethyl methacrylate. This mixture is generally packed in dry ice to avoid polymerization prior to use.*

The uninhibited liquid monomer must be maintained in the refrigerator to avoid premature polymerization. Under these conditions the liquid monomer can be maintained for several months.

Preparation of Specimens—The technique described below is intended especially for slices of organs.

The fresh specimen should be trimmed carefully and freed as much as possible of excessive fat and loose blood or fluid exudates. Slices of organs need not be limited in width to any size but they should be reasonably flat and should not exceed 2 cm in thickness. Organs or slices of organs which have a tough capsule should be freed of it if possible. This is particularly true of the kidney.

Freezing Freezing should be accomplished in a relatively short period of time, but instantaneous freezing is by no means necessary or even desirable. It is important not to allow the specimen to remain exposed to the dry atmosphere of low temperature cabinets for too long a period of time, in order to avoid superficial drying which would cause loss of color and distortion in the finished specimen. The best technique for slices of organs is as follows. Into a pan of proper depth, preferably metallic (although glass will do almost as well), pour water to a depth of about 1 cm and allow it to freeze and cool to a temperature of about -20°C . During this process a raised lump often forms in the middle. This should be carefully scraped off in order to have a perfectly flat surface. Immerse the specimen in water and while it is thoroughly wet lay it carefully on the formed base of ice. Allow it to freeze, so that it becomes firmly attached to the base of ice, then add in rapid succession thin layers of water (0.5 to 1 cm.) Each layer of water is allowed to freeze before addition of a new one. Continue the procedure until the whole specimen is covered with approximately 1 cm of ice (Fig 1). The block of ice is then removed from the form and trimmed so that there is no excessive ice on the sides. For whole organs, proceed as follows.

*This material is commercially known as Plexiglas. It can be obtained from the Pott and Haas Company, Philadelphia, Pa.

Prepare a base of ice as outlined. Place the organ, thoroughly wetted, on the base and allow it to freeze. When the specimen is thoroughly frozen and fixed to the base, with an atomizer spray it several times with a thin layer of ice. A layer of 1 or 2 mm in thickness is enough to protect the surface of the organ from drying and subsequent loss of color and shrinkage. The specimen is then completely imbedded in ice by addition of successive layers of water of about 1 cm in thickness. Carefully avoid pouring the water on the organ itself in order not to melt the glaze of ice.

Fig 1—The fresh specimen frozen and encased in ice

Before placing the frozen block in the drying apparatus it is desirable to chip off as much as possible the excess of ice in order to reduce the period of drying. Specimens may be preserved in the frozen state without appreciable deterioration for more than a year. This operation is not essential except as a timesaver. The ice blocks must be thoroughly chilled to -20°C or less before they are transferred to the drying apparatus.

Drying of Specimens From the Frozen State Any apparatus of proper capacity designed for the drying of biologicals from the frozen state can be used for this purpose. It must be capable of maintaining a temperature of -12 to -15°C or less in the specimen itself while the water is being removed by

sublimation. An apparatus previously described³ or any similar one has been found to yield excellent results. It is desirable to place the blocks of ice containing the specimens to be dried in a loosely tied bag made of a single layer of gauze (12 mesh). The wrapped specimens are placed in wire baskets or on supports of the same material and so arranged as to allow a free flow of the water-vapor. For medium sized specimens (approximately 5 to 7 cm in overall thickness and of any width fitting the drying chamber) and with the apparatus mentioned, five days are sufficient for complete drying. The water jacket heating the drying chamber should be maintained at a temperature of 37 to 40° C. Higher temperatures may be injurious to specimens containing large quantities of fat. Very large organs such as an entire brain require about ten days for complete drying. Certain specimens, for example an entire animal or fetus, containing trapped air, such as that contained in the gastrointestinal tract, or soft tissues in a hard or bony shell at times show some distortion from shrinkage in the final specimen. This can be avoided by drilling holes before freezing. Otherwise drying from the frozen state, when properly carried out, causes no distortion of the specimen nor loss of color or structure.

Trimming and Preservation of Dried Specimen. Once the specimen is dried it should be carefully maintained so by placing it in a glass desiccator containing a suitable dehydrating agent, such as magnesium perchlorate (trihydrate). Specimens may be kept in the dried state before imbedding for several weeks or even months without appreciable deterioration. For optimal results, however, the dried specimen should be unbedded as soon as convenient. The specimen can be trimmed with a very sharp knife in order to remove all loose portions and for the purpose of improving the specimen. It has been noted that retrimming of a slice of organ after drying for the purpose of obtaining a very smooth and even surface allows a much better view of the intimate structure of the tissue. Excessive fat can be removed readily at this time, avoiding damage to the specimen. Dust and loose particles must be removed carefully from the surface of the organ with a soft brush.

Saturation With the Liquid Monomer. The dried specimens appear to have lost their color and texture. These are restored immediately upon immersion in the liquid monomer at room temperature. It is most essential to obtain a very thorough saturation of the specimen with the liquid monomer, which entirely replaces all spaces previously occupied by water. This is accomplished by submitting the jar containing the specimen to a high vacuum in a protected desiccator. As a result of the procedure of producing a vacuum and releasing it many times in succession, it will be noted that the specimen will sink in the medium and will issue no more bubbles. At this stage the specimen is ready for the passage to the thickened monomer, unless it is desirable to prolong the immersion in the monomer for the purpose of removing excessive amounts of pigment, a procedure which should be applied to such organs as the liver. With specimens of liver or organs containing other diffusible pigments or fat, the liquid monomer should be changed a number of times during the process of saturation, until it remains clear and practically colorless.

*Preliminary Partial Polymerization of the Medium —**Equipment and Reagents*

1,000 cc Erlenmeyer or Florence flask (Pyrex)

500 cc of the mixed uninhibited monomer

100 mg benzoyl peroxide

Water bath, electrically heated and with spark proof switch

A chemical hood If provided with a motor driven aspirator the motor should be of the induction type (spark proof)

Procedure To 500 cc of the monomer in the Erlenmeyer flask add 100 mg of benzoyl peroxide Immerse the flask so that the level of the monomer is at the level of the water of the water bath maintained under a hood Bring the water to the boiling point The boiling point of the ethyl methacrylate is about 110 C, but the polymerization is an intensely exothermic reaction and the monomer will soon boil Remove the flask from the water bath the monomer will boil without additional heat Allow boiling to proceed for two to three minutes Carefully cool without unnecessary jarring but with a constant swirling motion under running cold water until bubbling ceases Continue cooling for approximately ten minutes until a temperature of about 40 to 45 C is reached Place in the refrigerator (4° C) until ready to use The material can be thus stored for several weeks

Since the vapors of methyl methacrylate are highly inflammable they should be kept from all open flames sparking switches motors and so forth If possible, place switches outside the hood At all stages the prepolymerization process should be closely observed since the reaction is intensely exothermic and the monomer will solidify or boil over and form an opaque mass

Amounts larger than 500 cc may be prepared However greater difficulty is encountered in cooling rapidly and therefore the monomer may go on to complete solidification

The consistency of the final product is directly proportional to the length of time the monomer is allowed to boil The times given here produce material which is about the consistency of extra heavy oil or molasses

Imbedding of Specimens —For the imbedding of specimens and the preparation of solid bases a temperature of 40 to 45 C is generally employed For this purpose any hot air oven may be used provided the thermoregulator is spark proof A thermoregulator of the sealed mercury type is satisfactory

When large specimens are imbedded the heat of polymerization may be sufficient to produce a temperature considerably higher than 40 to 45 C, and if the excessive heat is not rapidly dissipated bubbling will occur and thus spoil the specimen In these instances a proper temperature can be maintained by a blower, activated by a thermostat set to close the motor circuit at 46 C (Fig 2)

It is desirable to use glass containers for the final imbedding Metallic containers have not proved as satisfactory Ordinary square refrigerator storage containers or baking dishes as well as glass photographic trays have been used with good results It is preferable to prepare the receptacles with a hard base

of plastic on which to rest the specimen. This hard base is prepared by pouring into a clean dish of suitable size and depth a layer of about 2 cm. of the partly polymerized monomer. For this purpose very thick medium can be used. Cover the dish with two or three layers of cellophane, tightly fitted, and place in the refrigerator until the medium is absolutely free of air bubbles. Place at 45°C until the medium is entirely hard. The base is now ready to receive the specimen. The following procedure is recommended.

Fig. 2—Oven with blower

For flat slices of organs, or thin organs such as intestines, pour over the preformed hard base a small amount of the liquid monomer and with it thoroughly wet the base as well as the sides of the container. Pour the liquid off and drain rapidly. Pour over the hard base a layer of the thickened monomer calculated to be just enough to cover the specimen. If bubbles have formed, cover with cellophane and place in the refrigerator until they all have disappeared. Do not allow the poured thickened medium to stand for any period of time without a cover, particularly at room temperature or in the oven, because a tough film forms which renders subsequent operations difficult. When the medium is freed of air bubbles, remove the specimen from the monomeric medium and place it edgewise in the thickened medium by lowering it very gradually in such a manner as to avoid trapping air bubbles. It may be necessary at this time to add some of the thickened medium to cover the specimen completely, but under no condition add at this time a layer thicker than 2 to 3 centimeters. Cover the container with cellophane, and if air bubbles have been formed, replace in the refrigerator until clear. Then set in the oven at 45°C for polymerization. A block 3 cm. thick will harden in approximately one week.

at 45° C. Successive layers of 1 to 2 cm in thickness may be added to obtain a block of suitable size.

Imbedding of Large Irregular Organs The technique just described applies well to slices 1 to 2 cm thick of any organs such as liver, spleen, lymph nodes, thyroid, lungs, kidneys, tumors, and to flattened out specimens from large vessels, intestine, gall bladder, and so on.

Large irregular organs, however, such as heart, lung, uterus, brain, and whole liver require considerably more time and care. It is generally necessary

Fig. 3—Specimen imbedded in the block of transparent plastic

to begin the operation by preparing a base of suitable size. When this is obtained, the organ which is removed from the liquid monomer is coated with a thin layer of thickened monomer by immersion and placed on the base. The container with the base and the specimen is then very carefully sealed with many layers of cellophane or similar material. It is placed in the refrigerator so that it is thoroughly freed of bubbles and then placed in the oven at 45° C. This process is repeated until the organ is covered with a substantial layer. Great care must be exercised to cover the whole organ and to avoid trapping air bubbles. When the organ is thus glazed and fixed to the base proceed carefully to imbed it by adding successive layers not exceeding 5 cm in thickness in order

not to soften excessively the glazing on the organ. Whereas the imbedding of thin slices of organs offers no difficulty, the imbedding of entire large specimens challenges the skill and ingenuity of the operator. The results however are well worth the effort.

Finishing of the Specimen When the specimen is completely solidified, the edges of the plastic are detached from the glass with a sharp knife. On cooling, the blocks detach themselves from the walls of the container and will easily fall out with gentle tapping (Fig. 3). The finishing of the block is carried out as follows. The solid block first is rough-cut to the approximate size and shape of the final block desired with an ordinary band, circular, or jig saw. If a lathe is available it is well to turn the faces of the block down, since this will insure an absolutely flat surface. Since Plexiglas has machining qualities similar to those of brass and copper, metal cutting tools of this type can be used. A coolant (water, or soap and water) may be used if desired. If no lathe is available the block may be faced to a smooth (not accurately flat) surface by fastening emery paper to a block of wood and hand sanding with a circular motion. It is advisable to start the sanding with a coarse grade of emery paper and finish with a fine grade. If a sander is available the work may be accomplished much more quickly, but the final sanding should be a wet one, which will give a soft satin finish that can be buffed easily. Best buffing results are obtained with a very soft, open type of buffing wheel and an abrasive which is a combination of fine alumina with wax or grease binder, and a polishing tallow. The block, when finished, should have a high luster and be free from color and as transparent as the finest optical glass.

Reimbedding After Cutting of Imbedded Specimens To obtain a perfectly smooth surface of slices of organs or tumors, the imbedded specimen can be cut through with a fine band saw or similar tool and then polished as outlined to the point of a smooth, even, perfectly flat surface, or most of the clear block can be cut away and the specimen made flat by dry grinding. The specimen is then reimbedded as follows. Place the entire block with the exposed tissue surface uppermost in liquid monomer, and by means of high vacuum resaturate the tissue. Place face up in a suitable container and proceed to reimbed, following exactly the technique outlined previously. To surely avoid formation of bubbles on the raw surface of the exposed organ, it is desirable to store the specimen overnight in the icebox prior to polymerizing at 45° C.

Very thin, practically transparent sections can be obtained by proceeding as outlined and then cutting, polishing, and imbedding the other surface of the slice. These specimens are particularly valuable for teaching.

Removing Trapped Air Bubbles Trapped air bubbles can be removed from an otherwise satisfactory block by cutting and/or drilling with an instrument actuated by a high-speed motor, 5,000 revolutions per minute are satisfactory for this purpose. A tool with a flexible shaft is most desirable. Several types of drills may be obtained for practically any purpose.

Fig. 1. From "Report on the results of the work of the Department of Pathology, University of Chicago, 1934-1935".
C: specimen involved in disease, B: normal tissue, A: normal tissue.

Commonest Failures in Imbedding of Specimens in Plexiglas—These can be listed as follows

- (1) Loss of color Cause Previous fixation in formalin or prolonged immersion in liquid monomer
- (2) Shrunken portions Cause Incomplete immersion in water during freezing
- (3) Turbidity of the medium Cause Improper or incomplete drying, or excess of fat in the specimen
- (4) Formation of bubbles Cause Excessive heat during polymerization
- (5) Diffusion of pigment from the specimen Cause Too slow polymerization A common occurrence with certain specimens, such as liver
- (6) Disintegration of the specimen Cause Generally too prolonged exposure to monomer at high temperature
- (7) Fuzzing of the specimen at the periphery Cause Unknown Specimens thus affected may be cut so as to expose the inner portion and reembedded with good results
- (8) Formation of white precipitates Cause Unknown A not uncommon occurrence in imbedding very large specimens such as hearts and lungs Avoid prolonged immersion in partially polymerized methyl methacrylate by adding thin successive layers
- (9) Brittleness and loss of structure in cutting Cause Improper impregnation of dried specimen with liquid monomer

DISCUSSION

With the process described one can obtain preservation of the color and form of human specimens and similar material not possible with any other method known to us. These points are illustrated in Figs 4 and 5. Fig 4, A shows a fresh slice through a portion of a large xanthoma of the knee, with areas of hemorrhagic degeneration. Fig 4, B is the same specimen after drying and trimming. Fig 4, C shows the specimen imbedded in the finished block. Figs 1 and 3 show the same specimen frozen in a block of ice and at the stage of imbedding in the rough block of Plexiglas. Fig 5 shows the tumor preserved in a block of Plexiglas and a similar portion preserved in Klotz solution for a period of one year. Fading is already very noticeable in the specimen preserved in fluid.

For a slice of any organ up to 1 or 2 cm in thickness, it is approximately three weeks from the time the specimen is frozen to the time the finished block is obtained. The technique of cutting imbedded specimens, polishing the cut surface, and reembedding is recommended for optimal results. This process causes thorough impregnation of a perfectly smooth section of the specimen, particularly in such organs as liver, kidney, lung, and so on, thus permitting observations of minute details of the structure.

The technique for the imbedding of sections of organs, of tumors, or of entire animals can be said to be fairly well standardized and to produce fairly uniform and satisfactory results. Less constant results are obtained in im-

Fig 5—Left portion of a xanthoma of the knee preserved in Klotz solution for a period of one year
Right similar portion of the same tumor preserved in a block of Plexiglas

bedding entire large organs, such as an adult heart, lung or brain. With this type of material the results have been at times brilliant but not uniformly so, and failures have been just as common as successes. It is expected that improvement in the technique of imbedding and possibly in the preparation of the monomer employed may greatly aid the solution of the problem. With proper illumination, transparent blocks of Plexiglas containing organs or portions of organs have a particularly lifelike aspect. These specimens can be handled readily without danger of breakage and they remain absolutely unchanged for periods in excess of at least five years.

A CONVENIENT AND RAPID PROCEDURE FOR TOTAL CHOLESTEROL ESTIMATION USING AN ACID CHLOROFORM EXTRACTION

JOSEPH L. ZUCKERMAN AND SAMUEL NATELSON
BROOKLYN, N. Y.

THIS paper describes a simple rapid method for the determination of total cholesterol in blood serum.

The alcohol-ether extraction methods are time consuming because they require transfer and evaporation of the solvent¹⁻⁴. Recently methods have been reported for the determination of total cholesterol in one test tube by the addition of acetic anhydride directly to the blood serum in the presence of sodium sulfate⁵ or of dioxane⁶. These methods require procedures which need several hours for completion.

The method described herein will yield the desired result in approximately forty-five minutes. It lends itself to use in the routine laboratory in which large numbers of determinations must be done simultaneously. For example, thirty total cholesterol determinations in duplicate may be completed in two hours.

The present procedure depends upon the fact that dilute acids or alkalis, or saturated solutions of sodium sulfate, will split cholesterol from proteins in the presence of chloroform. Simultaneously, when this extraction is carried out in a shaking machine, the chloroform completely extracts the cholesterol.

The preferred procedure, therefore, consists of placing the serum in a test tube, adding dilute sulfuric acid and chloroform, stoppering the tube with a fat free rubber stopper, and centrifuging. The precipitated protein collects at the interface of the acid and the chloroform. The supernatant liquid and the protein button may be aspirated off with the aid of water suction and an aliquot of the chloroform layer taken. Acetic anhydride is added and the color is developed at constant time and temperature in the dark by the addition of concentrated sulfuric acid. This color may now be read in a photoelectric colorimeter.

When this extraction procedure is used, maximum color development occurs in seven minutes at 25 to 26° C. The color is therefore developed in a constant temperature bath at 25 to 26° C. and read after seven minutes.

Fig. 1 is a straight curve obtained by plotting concentration against the reading in a Klett-Summerson photoelectric colorimeter with a No. 60 filter. A similar curve is obtained using 625 m μ as the absorption beam with the Coleman spectrophotometer.

A box was designed to shake simultaneously 150 to 200 tubes for cholesterol extraction. This box is mounted on a standard large sized Kahn reciprocating shaker. Fig. 2 shows this box, made of five-ply wood, the partitions, and the rubber-faced plungers. This shaking box is also suitable for holding ten bottles in place and shaking them simultaneously.

From the Biochemistry Laboratory, Jewish Hospital of Brooklyn.
Received for publication June 8, 1948.

Fig 1—Standard curve plotting milligrams of cholesterol against Klett readings Total volume 3.1 milliliters

Fig. —Container with four compartments for shaking 150 to 200 stoppered test tubes
 A Wooden partition B rubber facing C movable wooden partition D metal rod E clamping screw
 F test tube G rubber stopper held in place

By moving the plungers forward and fixing them in place with set screws, the rubber-stoppered test tubes are held tightly in place as they are shaken back and forth

REAGENTS

10 per cent sulfuric acid (10 Gm of concentrated H_2SO_4 made up to 100 ml)

Chloroform, analytical grade

Acetic anhydride, analytical grade

Cholesterol standard, 0.2 mg per millimeter Forty milligrams of cholesterol recrystallized from acetone and dried are dissolved in less than 200 ml of acetic anhydride in a volumetric flask at 60° C, when completely dissolved, the solution is made up accurately to the 200 ml mark

Recovery solution, 0.025 mg per millimeter Fifty milligrams of cholesterol are dissolved in 200 ml of chloroform, 10 ml of this solution are diluted to 100 ml

Fat free stoppers No. 0 are allowed to soak in chloroform for about half an hour and then dried with gauze This is repeated each time before use

PROCEDURE

To a 15 ml test tube is added 0.1 ml of blood serum, to this is added 4 ml of 10 per cent sulfuric acid The acid should be blown from the pipette with force in order to prevent the protein from adhering to the walls of the tube To this are added exactly 4 ml of chloroform from a burette For the recovery study, 4 ml of the recovery solution are added instead of the 4 ml of chloroform The tube is then stoppered tightly and shaken in a shaking machine for twenty to thirty minutes It is then centrifuged The supernatant acid and the protein at the interface are then aspirated off with the aid of water suction. A 2 ml aliquot is now taken from the remaining chloroform, to which is added 1 ml of acetic anhydride This is done by touching the tip of the pipette lightly to silicone grease, inserting the pipette into the chloroform, blowing off the silicone grease, and aspirating the chloroform with a water aspirator The solution is mixed and 2 drops (0.04 ml) of concentrated sulfuric acid are added and the mixture is shaken vigorously The color is allowed to develop for seven minutes in a water bath at 25 to 26° C, in the dark, and then read on a Klett Summerson photoelectric colorimeter with a No. 60 filter, or on the Coleman spectrophotometer using 625 μ as the absorption beam

STANDARD AND BLANK

The standard is developed and read at the same time as the unknown It consists of 1 ml of the 0.2 mg per millimeter cholesterol standard, plus 2 ml of chloroform and 0.04 ml of concentrated sulfuric acid It is developed and read in the same manner as the unknown

The blank consists of 1 ml of acetic anhydride, 2 ml of chloroform, and 0.04 ml of concentrated sulfuric acid

CALCULATIONS

The concentration of the cholesterol in the unknown may be read off the standard curve Since this curve is a straight line the formula below will yield the cholesterol values in milligrams per cent when 0.1 ml of serum is used

$$\frac{\text{Density of unknown}}{\text{Density of standard}} \times 0.2 \times \frac{100}{0.05} = \text{mg \% of cholesterol}$$

RESULTS

The results obtained are listed in Table I. It is apparent that the results compare favorably with those obtained by extraction with Bloor's reagent. Table II indicates the amounts of cholesterol recovered when known amounts are added, as indicated under "Procedure."

TABLE I. COMPARISON BETWEEN THE KAYE METHOD AND THE AUTHORS' METHOD
(The values are expressed as milligrams per 100 cc of serum. Each value is the average of duplicates.)

SAMPLE	NEW METHOD	KAYE METHOD	SAMPLE	NEW METHOD	KAYE METHOD
1	228	219	6	184	182
2	300	289	7	208	209
3	189	189	9	139	139
4	309	307	9	213	216
5	202	195	10	165	262

TABLE II

NUMBER OF DETERMINATIONS	CHOLESTEROL ADDED	MEAN AMOUNT	AVERAGE DEVIATION FROM MEAN
18	0.1 mg	0.098	± 0.002

See Procedure for details.

SUMMARY

A convenient method is described for determining total cholesterol in sera employing a chloroform acid extraction.

The results are available within forty five minutes after the beginning of the determination.

The results are comparable to those obtained with Bloor's method of extraction.

This procedure is recommended where large numbers of determinations are required in a short time.

METHODS FOR THE CHEMICAL DETERMINATION OF CORTICOSTEROIDS IN URINE AND PLASMA

A C CORCORAN, M D , AND IRVINE H PAGE, M D
CLEVELAND, OHIO

THE methods here described derive from one suggested in abstract¹ but found inadequate. The underlying principles are extraction and partial separation of neutral steroids from urine or plasma and oxidation of the α ketol or α glycol side chains of the C_{21} steroids of adrenal cortical origin with periodic acid² followed by colorimetric measurement of the formaldehyde formed in the oxidation.³ Oxidation and colorimetry proceed in the manner described for determination of mannitol⁴ with the exception that formaldehyde is distilled from the reagent mixture before treatment with the chromogenic reagent. This modification has been described independently⁵ for determination of urinary cortisol in a procedure which corresponds generally with the one here described.

The greater specificity of a procedure which depends on periodic oxidation as compared with sugarlike reduction of copper reagents is now accepted by many workers in the field. It is therefore desirable to present together analogous methods for estimation of corticosteroid in both urine and plasma which include this principle.

APPARATUS

All glass, standard taper flasks, distillation apparatus and semimicro flasks and condenser. Tall (200 x 20 mm) glass test tubes calibrated at 10 or 12.5 cc, Lewis and Benedict blood sugar tubes are suitable.

Spectrophotometer* or other suitable photocolometric apparatus

Automatic pipette (5 cc) for rapid, free delivery of chromotropic acid reagent

REAGENTS

Solvents (1) Chloroform, chemically pure, redistilled (2) Glacial acetic acid, Baker special (emphysema free) (3) Alcohol ether 3 volumes 95 per cent alcohol to 1 volume of ethyl ether (4) Petroleum ether, boiling point, 30 to 60° C (5) Acetone, chemically pure

Sodium sulfate, anhydrous

Sodium hydroxide, 0.1N

Saturated aqueous solution of magnesium chloride

Periodic acid reagent Potassium periodate, 0.03M in 0.25M sulfuric acid

Stannous chloride reagent Prepared daily by dissolving about 1.4 Gm stannous chloride in 50 cc of 2.5N HCl. The solution is titrated to a starch end point with periodic acid reagent and adjusted so that 10.2 cc of periodic acid reagent oxidizes 10 cc of stannous chloride reagent.

Chromotropic acid reagent Dissolve 0.2 Gm of chromotropic acid (1,8 dihydroxynaphthalene sulfonic acid) in 4 cc of water in a 100 ml volumetric flask and make up to volume with 15M sulfuric acid. The solution is prepared daily.

Approximately 9M sulfuric acid

PROCEDURE

Urinary Corticosteroid—

Collection and Extraction A twenty four or twelve hour night urine sample is collected. Depending on the adequacy of refrigeration and the speed of beginning extraction no preservative need be added or there may be added 5 cc of chloroform or 1 cc of 1 per cent aqueous Merthiolate (Lilly).

A four or six hour aliquot of the sample is brought to about pH 10 with concentrated HCl, 100 cc of chloroform are added. The mixture is shaken once and refrigerated until analyzed.

The urine is extracted four times with 100 cc portions of chloroform by shaking for fifteen minutes with each portion. The urine layer is discarded from a separatory funnel and the combined extracts and emulsions are centrifuged. The remaining urine layer is discarded. The extracts and emulsions are combined and dried by addition of sodium sulfate. The clear supernatant extract is filtered through glass wool.

This extract is chilled, washed twice with 0.1 volume of cold 0.1N NaOH and once with water. Each washing is back extracted with an equal volume of chloroform. These extracts are added to the washed chloroform extract and the NaOH and water are discarded.

The washed chloroform extract is evaporated in vacuo at less than 30°C in an all glass distillation apparatus to a volume of about 10 cubic centimeters. At this point the extract is divided in two equal portions and each is quantitatively transferred by rinsing with small volumes of chloroform into round bottomed distillation flasks of 25 cc capacity. Evaporation is continued to dryness.

Colorimetric Assay (1) Oxidized sample. The dried residue from one of the two flasks is dissolved with 0.5 cc of glacial acetic acid. When the flask residue is thoroughly wetted, 8.5 cc of water are added and to the mixture 0.5 cc of periodic acid reagent is added. The mixture is allowed to stand at room temperature for thirty minutes when oxidation is arrested by addition of 0.5 cc of stannous chloride reagent. (2) Unoxidized sample. The residue is brought into solution as described and made up with water to 9 cubic centimeters. Then 0.5 cc of stannous chloride reagent is added followed immediately by 0.5 cc of periodic acid reagent. (3) Blank on reagents. Oxidized and unoxidized reagent blanks are prepared from volumes of all reagents equal to those used in analysis.

The distillation flask is attached to a semimicro condenser. The elongated outlet tube of the condenser is placed under the meniscus of 10 cc of water in a 10 cc volumetric flask. About 8 cc of distillate are collected by careful heating over a microburner. The distillate is then made up to volume with water.

Three cubic centimeters of distillate are placed in a tall glass test tube and 5 cc of chromotropic acid reagent are rapidly mixed in. The tube is placed in a boiling water bath for thirty minutes. At the end of this time it is rapidly cooled to 25°C made up to volume (10 or 12.5 cc) with 9M sulfuric acid and stabilized to 25°C in a water bath. Color density (D) is measured at 570 m μ rons.

Calculation The color density due to liberation of formaldehyde from the unoxidized sample is subtracted from the color density of the oxidized sample. From this is subtracted the corresponding color density obtained from the difference between oxidized and unoxidized blanks. The resultant color density represents formaldehyde liberated from corticosteroid like substances in the extract of urine. The amount present is found by reference to a calibration curve prepared from oxidation and colorimetry of desoxycorticosterone in 20 per cent alcohol. The result is expressed as milligrams corticosteroid per twenty four hours.

Plasma Corticosteroid—

Collection and Extraction The plasma from about 50 cc of fresh heparinized blood is added drop by drop with stirring to 5 volumes of 3:1 alcohol ether. The protein precipitate is collected on a sintered glass filter and thrice extracted by washing with 50 cc portions of alcohol ether. The filtrates are combined and the protein residue is discarded.

The combined alcohol ether extract is evaporated under reduced pressure at less than 30°C to a volume of about 30 cubic centimeters. To the substantially aqueous residue 20

per cent alcohol is added to make a solution containing about 70 per cent alcohol. This solution is extracted three times with equal volumes of petroleum ether. The petroleum ether washings are then discarded.

The clear, aqueous alcohol extract is evaporated in vacuo to a volume of about 5 cubic centimeters. Fifty cubic centimeters of acetone are added to the residue and 5 drops of saturated magnesium chloride reagent are stirred in. The mixture is allowed to stand in the cold for at least one hour. The clear, supernatant acetone extract is decanted through a sintered glass funnel. The gelatinous precipitate of phosphatide remaining is dissolved in portions of water and 95 per cent alcohol of 3 and 15 cc volume respectively. The solution of phosphatide is then evaporated in vacuo to a volume of about 1 cc, when the precipitation with acetone and magnesium chloride is repeated as described. The acetone extracts are combined and brought to dryness in vacuo. Should the residue from this evaporation have any considerable bulk it should be dissolved in alcohol and water and the precipitation repeated again.

The all but imperceptible residue from the acetone extract is taken up in 50 cc of chloroform and chilled. The cold extract is then washed with cold 0.1N NaOH in the manner described for urine extract. It is then dried by addition of sodium sulfate, filtered through sintered glass, and divided into two samples of equal volume. These samples, to be oxidized and not oxidized respectively, are brought to dryness in 25 cc distillation flasks as described.

Colorimetry and calculation are done in the manner described for urine. The result is expressed as milligrams per 100 cc of plasma.

RESULTS

Urinary Corticosteroid—The formaldehyde-forming content of adrenal cortical extract added to samples of urine and carried through the procedure was recovered in a proportion which averaged 80 to 90 per cent. Values obtained from analyses of twelve-hour night urine in ten normal male and female subjects

TABLE I AMOUNT OF CORTICOSTEROID LIKE SUBSTANCE PRESENT IN URINE OF NORMAL MALE AND FEMALE SUBJECTS

MALE SUBJECT	MG /24 HR.	FEMALE SUBJECT	MG /24 HR.
1	0.77	1	1.43
2	1.41	2	.48
3	1.66	3	1.63
4	1.33	4	.76

7	0.94	7	.28
8	0.72	8	.43
9	1.57	9	.32
10	0.81	10	.65
Mean	1.15		0.84
	± 0.32		± 0.29
Mean for whole group	0.995 mg /24 hr		

These values were obtained from analysis of twelve-hour night urine and are expressed as milligram of desorycorticosterone per 24 hours.

are shown in Table I. Redeterminations on twenty-four hour urine specimens from eight of these subjects show no difference from the mean value found with night urine nor any consistent variations between day and night corticosteroid output. Values found in various abnormal situations and conditions are listed in Table II. Deviations from the normal in the latter series correspond well with clinical prediction. The values found are comparable to those obtained by Daughaday, Jaffe, and Williams,⁶ and the methods, as noted, differ only in certain particulars.

TABLE II OBSERVATIONS ON URINARY CORTICOSTEROID LIKE SUBSTANCES IN VARIOUS CLINICAL CONDITIONS

PATIENT	SEX	DIAGNOSIS	TREATMENT	RESULT (MG /24 HR)
1	M	Malignant hypertension		0.91
			Pyrogen 3 days	2.34
			Pyrogen 6 days	4.4

12	F	Acromegaly		0.91

Plasma Corticosteroids—Recovery of the formaldehyde forming substances in adrenal cortical extracts added to plasma ranged from 85 to 100 per cent in six determinations. Values found in the venous blood of normal human beings and in normal dogs are listed in Table III. The means in the two groups were 0.25 mg per 100 c.c. of plasma.

TABLE III CORTICOSTEROID CONTENT OF BLOOD PLASMA

MALE SUBJECT	MG PER 100 c.c.	FEMALE SUBJECT	MG PER 100 c.c.
<i>Normal Human Beings</i>			
1 a	0.42	1	0.34
b	0.38		
2 a	0.20	2	0.20
b	0.11		
3	0.23	3	0.13
4	0.16	4	0.42
5	0.14		
<i>Normal Dogs</i>			
0.74	0.38	4.47	0.25
4.45	0.12	5.12	0.12
4.73	0.27	0.12	0.50
4.84	0.21		
5.03	0.38		

Variations of the level were found in normal male human Subject 1 in a value of 0.98 mg per 100 c.c. thirty six hours after a second and third degree burn. This value fell to 0.38 mg per 100 c.c. on the tenth day. Dog 0.12 yielded levels of 0.30 before and 0.6 mg at twenty four hours after administration of a bacterial pyrogen. Concurrent urinary corticosteroid values in this animal were 0.15 mg per twenty four hours during the three day period before pyrogen injection and 0.38 mg per twenty four hours in the three days after treatment. Variations in plasma level thus correspond with clinical prediction.

The validity of the method is further confirmed in experiments conducted with the assistance of Dr. John Reinhard. In these the left adrenal efferent vessels of dogs were ligated and a segment of the lumboadrenal vein was isolated.

by ligatures where it passes under the gland. A plastic catheter was inserted into the vein and brought out through the abdominal incision which was closed. The operations were done under pentobarbital anesthesia and after administration of heparin. Adrenal venous blood was then collected over varying intervals. Blood loss was partially compensated for by transfusion of whole dog blood, of gelatin, and of washed red blood cells after separation of plasma.

The courses of three such experiments are shown in Fig 1, which demonstrates the levels of corticosteroid output in the venous plasma of the left adrenal

Fig 1—Output of corticosteroid (corticoid) into left adrenal venous plasma in three dogs at varying intervals after cannulating the isolated lumbal adrenal vein. Effect of injection of epinephrine (E) time of injection is indicated by arrows. Abscissa minutes after starting collection.

Corticosteroid content of adrenal venous plasma at intervals indicated by time of collection in minutes before (A) and after (B) injection of epinephrine into the femoral vein. Output is calculated by multiplying plasma concentration by adrenal venous plasma flow.

gland in milligrams per hour and the effects thereon of administration of epinephrine in doses of 0.2 to 0.5 mg into the femoral vein. Concentrations of corticosteroids in adrenal and peripheral venous plasma and the steroid outputs as well as simultaneous measurements in peripheral blood are listed in Table IV. The concentrations found in the adrenal venous plasma were higher than those obtaining in peripheral blood. The steroid output in these experiments averaged 0.85 mg per hour at the outset. In four of six experiments in which measurements were made the increased corticosteroid output caused by epinephrine was reflected in an increase in the concentration present in peripheral blood. However, we direct attention to these experiments (which will be reported in more detail) to confirm the method proposed rather than to deal with physiologic variations in the adrenal steroids.

DISCUSSION

Urinary Corticosteroid—Identification of urine before extraction follows the recommendation of Heard, Sobel, and Venning.⁷ Extraction is carried on four times to yield satisfactory recoveries of added adrenal cortical extract. Thus recoveries with two, three, and four extractions are 31, 65, and 94 per cent respectively.

The crude chloroform extract is washed with sodium hydroxide in the manner of Talbot, Salzman, Wixom, and Wolfe.⁸ The washing reduces the bulk of the residue and thus reduces the probability of nonspecific contamination of the material which is to be oxidized. Other data⁸ suggest that this step is not essential. However, on several occasions the residue from washing with water and alkali has been shown to contain small but significant amounts of chromogenic material.

The residue from the washed chloroform extract is dissolved in glacial acetic acid because of the good wetting quality of this reagent. The residue is not partitioned with benzene and water as was proposed¹ or as recently described² because of the incompleteness of water extraction of certain steroids from benzene (Heard and Sobel⁹) and because the benzene-water partition of adrenal cortical extract yields a ratio of color density in benzene as compared with water of about 0.65.

Distillation of formaldehyde is done because of interfering colors which form during the heating of urinary or adrenal cortical extracts in the strong acid of the chromotropic acid reagent. The distillate is not received in sulfite as in the method of Daughaday, Jaffe, and Williams⁵ because formaldehyde can be quantitatively recovered in water. It is important to distill a sufficient volume. With distillate volumes of 4.5, 5.0, 5.5, 8.0, and 8.5 cc, the respective recoveries of formaldehyde are 63, 75, 78, 99, and 101 per cent.

Mason⁶ developed an almost identical procedure. In his method as in ours fractionation of the steroid extract with Girard T reagent⁸ is omitted because results on unfractionated extracts parallel those obtained with the more tedious fractionation. It may be of interest to note that, in our hands, the ketone

Minn. We acknowledge the cooperation and advice of Dr. H. L. Mason, Mayo Clinic, Rochester.

fraction in urinary extracts accounted for about one-third of the total oxidizable steroid *

Plasma Corticosteroid—The desirability of determinations of plasma corticosteroid is suggested by the fact that the amount measured in human urine averages about 0.05 per cent of the amount circulating through the kidneys. Rephrased, the urinary plasma clearance of corticosteroid is only 0.11 cc per minute. The apparent threshold of excretion is therefore very high, as indeed it should be for a material so important in bodily function. However, the inference is that under certain conditions measurements of plasma corticosteroid may have greater diagnostic and physiologic value than measurements in urine. This is especially true in experiments of brief duration, such as after injection of epinephrine.

The feasibility of such a determination was demonstrated by Hemphill and Reiss.¹⁰ Their procedure measured corticosteroid by applying to plasma extracts the method of Talbot, Salzman, Wilcox and Wolfe,⁸ while the method here presented has the advantages of the procedure described for urine extracts. As compared with the method of Hemphill and Reiss¹⁰ the extraction process has been elaborated. Thus, we have found it essential to precipitate out phosphatide and, apparently because of entrapment of corticosteroid onto the phosphatide precipitate, the precipitation has to be repeated more than once. Further, an interfering chromogen is separated by washing plasma extract in 70 per cent alcohol with petroleum ether. Preliminary experiments indicate that it may be more convenient to make the first extraction by adding plasma to acetone containing 2 per cent chloroform. In a personal communication, Dr. O. M. Hechter¹ suggests that direct extraction of whole blood or plasma with chloroform is also satisfactory. Thus, while it is apparent that modifications can be made in the procedure, it is presented here in the form in which it has been most extensively tested.

As noted previously, observations on the corticosteroid output of the adrenal in dogs and the effects thereon of adrenalin are not the focus of this communication. Still it is of interest to note that the experiments listed here confirm the observations Vogt has made by bio-assay.¹¹ Thus, she estimated output of active steroid at about 230 cc. Eucoitone per twenty-four hours in a dog weighing 10 kilograms. Our estimate in terms of Upjohn adrenal cortical extract analyzed by oxidation and colorimetry would be about 88 cubic centimeters. Again, Vogt showed an increase of hormone output after injection of epinephrine. This estimate is confirmed in Fig. 1. In Table IV we also show that increased output due to epinephrine is often reflected in an increase in the corticosteroid content of peripheral as well as adrenal plasma.

As might be surmised, simple modifications enable the application of the plasma procedure to samples of tissue.

SUMMARY

Methods are presented for the estimation of corticosteroids in urine and plasma. The underlying principles are (1) extraction and partial separation

*We would also note the helpful interest of Dr. Eleanor Venning of the Royal Victoria Hospital, Montreal, Canada.

†Worcester Foundation for Experimental Biology, Shrewsbury, Mass.

of neutral steroids from urine or plasma, (2) oxidation of the side chains of the C₁₉ steroids of adrenal cortical origin by means of periodic acid and (3) colorimetric measurement of formaldehyde formed in the oxidation. Values found in normal subjects are listed, together with illustrative clinical and experimental observations which indicate the application of these procedures.

The authors take pleasure in noting the skillful assistance of Mr. Frank Ungar, B.A. M.S., in the development of the plasma procedure and of Mrs. Lorraine Friedman, B.A. in the urine method.

QUICK MICROTECHNIQUES FOR THE IDENTIFICATION OF CULTURES

I INDOLE PRODUCTION

W M ARNOLD, JR, B S, AND R H WEAVER, PH D
LEXINGTON, KY

THE bacteriologist has always been handicapped in identification of organisms, as compared with other biologists, by the fact that the organisms with which he deals cannot be identified by their morphologic characteristics alone. The necessity of including cultural and biochemical characteristics has made identification a time-requiring procedure. Cultures need time to grow and to produce biochemical reactions.

In the diagnostic laboratory especially, the value of bacteriologic work definitely has been limited by the time required to isolate and identify the organisms from the patient. In addition, bacteriologic work often becomes expensive because of the time required and the materials and equipment needed. The chemist has partially solved the problem of expense by the development of semi-micro- and microtechniques.

This study of indole production was undertaken to see if microtechniques could be applied to the study of biochemical reactions of microorganisms and if, at the same time, results could be obtained in a shorter period of time.

The principle on which the test is based is the use of small amounts of media and large inoculums to allow the organisms to start growing without appreciable lag phases and to produce, in a short period of time, sufficient concentrations of biochemical products to be detectable if sensitive reagents are used. Studies have been made to determine the optimum conditions for indole production and detection by the microtechnique.

DEVELOPMENT OF THE MICROTECHNIQUE

Tests proved to be most satisfactory with 1 ml quantities of medium in 10 by 75 mm tubes. Smaller tubes were not practicable because of difficulty in mixing the test solution with the medium.

For the detection of the indole, the Ehrlich, Kovács,¹ and Gore methods were tried. For the preliminary testing of these methods a medium containing 10 per cent tryptone and 0.3 per cent beef extract was used. Tubes of this medium were heavily inoculated with a stock strain of *Escherichia coli*. Tests for indole were performed on these tubes after periods of incubation at 37° C for from two and one-half to six hours. With the Kovács method a doubtful reaction was obtained in one of two tubes after three hours of incubation, and a strongly positive reaction was obtained in all the tubes that were incubated for four hours or longer. The other two methods were less sensitive, requiring

From the Department of Bacteriology University of Kentucky
Received for publication June 30 1948

at least one hour more of incubation to obtain comparable results. Because of these results and because its application is simplest Kovacs' method was selected for all subsequent work.

In the test, four drops of fresh Kovacs reagent are added to the 1 ml quantity of medium in the tube. The tube is shaken and the results are read after a few minutes. In the early part of the work the chloroform solubility test of Fellers and Clough³ was used to check the specificity of the positive reactions. Since these reactions always proved to be specific this test was discontinued later. The Kovacs reagent must be fresh. Upon standing at room temperature its color changes from yellow to brown and it becomes less sensitive. It may be preserved for several days in the refrigerator. For the preparation of the reagent, various brands of amyl alcohol, isomyl alcohol and isobutyl alcohol were tried. Of these the isomyl alcohol proved to be superior, some of the amyl alcohols giving false colorations and the isobutyl alcohol failing to separate sharply from the medium.

After a study of a number of media two were selected for use in the micro technique. Medium 1 consisted of 1.0 per cent tryptone and 0.3 per cent beef extract, in distilled water. Medium 2 consisted of 0.03 per cent tryptophane, 0.1 per cent peptone, and 0.5 per cent K_2HPO_4 in distilled water. It was found that in Medium 1 a salt mixture consisting of 0.1 per cent $NaCl$, 0.02 per cent $MgSO_4$, 0.01 per cent $CaCl_2$, and 0.1 per cent K_2HPO_4 , could be substituted for the beef extract without affecting the results. Since the salt mixture added to the complexity of the medium without adding to its productiveness it was not used in later tests of the technique. The addition of either beef extract or the salt mixture to Medium 2 did not affect the results obtained. For the peptone in Medium 2 Coleman and Bell Bacto peptone, Bacto proteose peptone, 3 Bacto tryptone and Bacto tryptose were tried. All gave equally good results.

The addition of 0.6 per cent agar to Medium 1 caused false colorations to be produced with the test reagent. A medium consisting of 1.0 per cent Bacto peptone and 0.3 per cent beef extract was found to be unsuitable for use in the micro technique.

Batches of Medium 1 and of Medium 2 with pH values varying from 7.0 to 8.0 were tried. Equally good results were obtained with pH values between 7.4 and 7.8. At pH 7.0 and pH 7.2 indole was formed as quickly as at the higher pH values but the amount formed was less. For example in one experiment indole was formed at all pH values between 7.0 and 7.8 in six minutes, either doubtful or weak reactions being obtained. After fifteen minutes of incubation all tubes with pH values between 7.4 and 7.8 yielded strongly positive reactions whereas those with pH values of 7.0 and 7.2 yielded doubtful or weak reactions. In the later use of the micro technique all media were adjusted to pH 7.4.

The testing of a large number of cultures with Medium 1 and Medium 2 indicated little difference in value for the two media. No discrepancies in results have been noted. With many cultures the time required for indole production in Medium 2 from tryptophane is about one third less than the time required

for production in Medium 1, from tryptone. This saving in time may not be considered sufficient to warrant the use of the more expensive Medium 2.

Quick production of indole depends upon rapidly obtaining the incubation temperature of 37° C. Preheating of the tubes of medium before inoculation shortens materially the time required for indole production. Water bath incubation instead of hot air incubation also helps. Usually if a culture will produce indole in two hours without preheating of the medium it will do so in from thirty minutes to one hour with preheating and in from eighteen to thirty minutes with water bath incubation. We have obtained indole production in six minutes with water bath incubation.

Absolute sterility has been found to be unessential with the microtechnique. In this study the tubes and the medium were always sterile but a relative absence of contaminants is probably all that is necessary. Cotton plugs do not need to be used. A small number of contaminants cannot multiply rapidly enough to affect the results of the test.

The size of inoculum is important. Inoculation of a tube with all the growth obtainable from a colony with a diameter of 2 mm will give good results. Inoculation with the larger amount of growth obtainable from an agar slant culture will yield somewhat quicker indole production. Inoculation with growth from a culture which is in the logarithmic period of development will give quicker results than inoculation from an older culture.

COMPARISON OF MICROTECHNIQUE WITH GNEZDA TECHNIQUE

For testing the accuracy of results obtainable with the microtechnique, comparative tests were made with the Gnezda⁴ technique. For the Gnezda technique tryptone broth was used and incubation was at 37° C for four days.

Results with the two techniques were identical. Cultures which gave positive results were fifty-seven strains of coliforms, three strains of *Pseudomonas caviae*, two strains of *Proteus munitilis*, and one strain each of *Proteus vulgaris* and *Shigella paradysenteriae*. Of these, two of the strains of coliforms yielded weakly positive results with the Gnezda technique after four days. All the other strains gave strongly positive results with both methods. Cultures which gave negative results were three strains of coliforms, nine strains of unidentified soil organisms, and one strain each of *Salmonella schottmulleri*, *Salmonella paratyphi*, *Salmonella enteritidis*, *Vibrio comma*, *Pseudomonas aeruginosa*, and *Pseudomonas fluorescens*. The majority of the strains of coliforms were fresh isolates and the tests were made with inoculums from the primary colonies on the selective media used for isolation. All other cultures used were stock strains.

The rapidity with which indole was formed in the microtechnique raised the question as to whether the indole was being formed because of growth or the organisms and enzyme production during incubation or because of preformed enzymes that were present in the large inoculum. In this connection we were interested in determining the effect of the medium from which inoculum was taken on the rate of indole formation.

From thirteen strains of coliform organisms, streaks were made on nutrient agar plates and on tryptone agar plates. After a twenty-four hour period of

incubation, tests for indole forming ability were made by the microtechnique with inoculums from both types of plates. Of the thirteen strains, ten gave positive indole tests after one and one half hours when the inoculums were taken from the nutrient agar plates. Of these, one gave a positive test after eighteen minutes, five after thirty six minutes, two after one hour and two after one and one half hours when the inoculums were taken from the tryptone agar plates. Thus growth of the inoculum culture on tryptone agar appeared, in the majority of cases, to increase the speed with which indole was produced.

Using the two strains of coliforms that had produced only traces of indole after two hours, an attempt was made to increase the rate or amount of indole formation by transferring for two generations on tryptone agar plates. No increase in rate or amount of indole formation occurred.

The laboratory strain of *Escherichia coli* was grown for four generations on a synthetic tryptophane free medium. At the end of this time indole determinations were made using colonies from the synthetic medium, from nutrient agar plates, and from tryptone agar plates as sources of inoculum. Again indole was formed more rapidly in the tubes that had been inoculated from colonies on the tryptone agar plates. Surprisingly however indole was formed slightly more rapidly in the tubes that had been inoculated from the synthetic medium than in those that had been inoculated from the nutrient agar plates.

From this series of experiments it may be concluded that the medium from which the inoculum is taken has only a minor effect on the results of the micro technique for the determination of indole producing abilities of bacterial cultures.

SUMMARY

A quick microtechnique for the determination of the abilities of microorganisms to produce indole has been described. Heavy inoculations are made into 1 ml quantities of medium in 10 by 75 mm tubes that have been preheated to 37° C. Either tryptone broth or a synthetic medium containing tryptophane has been found to be satisfactory. The tubes are then incubated at 37° C preferably in a water bath. Indole may be detected in the tubes upon the addition of 4 drop quantities of a fresh Kovacs solution which has been made with isoamyl alcohol as the solvent. The period of incubation that is necessary has been found to vary from six minutes to two hours depending upon the strain of organism, the age and size of inoculum and the method of incubation.

QUICK MICROTECHNIQUES FOR THE IDENTIFICATION OF CULTURES

II FERMENTATIONS

JOHN HANNAN, B S, AND R H WEAVER, PH D
LEXINGTON, KY

SUCCESS in developing a quick microtechnique for the detection of indole producing abilities of microorganisms (Arnold and Weaver¹) led to an attempt to develop a similar technique for the demonstration of fermenting abilities of microorganisms. The principle on which the test to be reported is based is the same as that used in the test for indole production, namely the use of small amounts of media and large inoculums to allow the organisms to start growing without appreciable lag phases and to produce, in a short period of time, sufficient concentrations of biochemical products to be detectable if sensitive reagents are used.

DEVELOPMENT OF THE MICROTECHNIQUE

The microtechnique was developed using cultures of the Enterobacteriaceae as test organisms. Thus far its use has been limited to this group of organisms.

Tests proved to be most satisfactory with 0.15 ml quantities of medium in 5 by 50 mm tubes. Larger tubes, 10 by 75 mm, containing 0.5 to 1.0 ml quantities of medium could be more easily handled, but their use in place of the smaller tubes approximately doubled the time required for the demonstration of fermentation.

Of a number of basal media that were investigated, all but one was discarded as unsatisfactory. Thioglycollate broth, nutrose solution, neopeptone solution, and neopeptone and tryptone solution were discarded because the rate of fermentation in them was too slow. A yeast extract medium was discarded because the yeast extract contained some substance or substances that would allow the production of both acid and visible gas by *Escherichia coli* cultures under the conditions of the microtechnique.

The following basal medium was selected for use: Difco beef heart infusion 7.5 per cent, proteose peptone 3, 1.0 per cent, KH_2PO_4 0.1 per cent, NaCl 0.5 per cent, distilled water, pH 7.0. Indicator: 5 ml of a 1.6 per cent alcoholic solution of bromocresol purple and 5 ml of a 1.6 per cent alcoholic solution of cresol red per liter of medium.

This medium proved to be free of fermentable substances when it was tested with strains of *E. coli*. Later it was found that controls of this basal medium that had been inoculated with *Aerobacter aerogenes* showed slight visible gas formation, although by the usual macrotechniques *A. aerogenes* could not be shown to produce any fermentation in the medium. It was therefore necessary

From the Department of Bacteriology, University of Kentucky.
Received for publication June 30, 1948.

to remove the fermentable substances from the beef heart infusion by fermentation with *A. aerogenes*. The beef heart infusion was dissolved in the distilled water. This solution was inoculated with 5 ml of a twenty four hour nutrient broth culture of *A. aerogenes*. It was then incubated at 37° C until bubbles ceased to appear approximately forty hours. The organisms were removed by passage through a filter pad*. The remaining ingredients were then added to this infusion, and the resultant medium was adjusted to pH 7.0. This basal medium was then sterilized by autoclaving.

When the tests were to be run a sufficient quantity of a 20 per cent solution of the carbohydrate to be tested to produce a final concentration of 5 per cent was added to the basal medium. It was found that the carbohydrate solution had to be sterilized by filtration. The use of autoclaved solutions resulted in false reactions by the microtechnique even when the use of the same solutions in medium for tests by the macrotechnique did not. The final medium was then dispensed in the small tubes with capillary pipettes. In all the work reported upon in this study sterile pipettes and sterile tubes were used but it has been found that only relative sterility is necessary. Cotton plugs may be omitted. It was found that the time required for the test could be reduced by preheating the tubes of medium in the water bath previous to inoculation.

If inoculation is to be with liquid medium cultures or with suspensions of the organisms in saline the medium should be prepared in double strength to allow for dilution of the medium with the liquid of the inoculum.

The inoculum should be large. The time required for the test will be shortened if the culture from which the inoculum is taken is in the logarithmic growth period. Inoculation from growth on a solid medium with a platinum needle is satisfactory. In this study most of the inoculations were made with suspensions that had been prepared by emulsifying growth from an agar slant culture or from a colony in a small amount of sterile saline. Inoculations were made in this case by adding 0.15 ml quantities of the suspensions to the medium in the tubes by means of capillary pipettes.

The inoculated medium was then capped with a 3 mm layer of 1 per cent agar in distilled water to which indicator had been added in the proportion of 1 ml each of a 1.6 per cent alcoholic solution of biomercol purple and a 1.6 per cent alcoholic solution of cresol red per liter. The indicator was added to the agar solution to detect any change in pH due to absorption of acid substances from the air during storage. When this precaution was not taken, the reading of the results was occasionally confused by a small area of acid reaction at the junction of the agar solution and the culture caused by an agar solution that had become acid. Less indicator was added to the agar than to the medium to make the junction of these solutions more discernible.

The capping is done with a capillary pipette. The melted agar is permitted to flow down the inside wall of the tube. Care must be taken to avoid bubbles. If bubbles form they can usually be eliminated from the agar medium interface by a gentle tapping of the tube.

The quickest results are obtained by incubation in a 37° C water bath. This is due to the fact that the medium reaches the incubation temperature much more quickly in the water bath than it does in a hot air incubator.

Acid production may first be noted by the production of a yellow color just beneath the agar cap. Readings must always be made by comparison with inoculated controls of the basal medium that do not contain the test carbohydrate. If this is not done, false results may be obtained because of transference of acid to the medium with the large inoculum. Gas production is evinced by the collection of bubbles at the agar-medium interface. Acid production usually may be detected before gas production, but the opposite is occasionally the case.

RESULTS WITH MICROTECHNIQUE

Results with the microtechnique were compared with those with the macrotechnique on five strains of *A. aerogenes*, five strains of *E. coli*, ten strains of paracoli, ten strains of *Salmonella*, three strains of *Eberthella typhosa*, five strains of *Shigella*, and seven strains of *Proteus* using glucose, mannitol, sucrose, lactose, and maltose. The macrotechnique was run using Durham fermentation tubes and nutrient broth base plus filtered sugar solutions. Final results were read after seventy-two hours. Two determinations were made with the microtechnique. In the first, the tubes were inoculated with suspensions obtained by emulsifying single colonies from nutrient agar plates in 1 ml quantities of sterile distilled water. In the second, the tubes were inoculated with heavy suspensions obtained by emulsifying growth from twenty-four hour cultures on brain-heart agar slants.

The essential features of the results are summarized in the following statements.

Identical results were obtained with the macrotechnique and with both sets of microtechnique determinations.

The use of a heavy inoculum materially shortens the time required to obtain results with the microtechnique. With the light inoculum, acid production was obtained in from 15 to 725 minutes and gas production in from 75 to 660 minutes. With the heavy inoculum, acid production was obtained in from 10 to 230 minutes and gas production in from 35 to 240 minutes.

The simplest fermentable substances were fermented more rapidly than were the disaccharides. For example, with the six strains of organisms that fermented all the substances that were tested and with the light inoculum, an average of 95 minutes was required for production of acid from glucose, 85 minutes from mannitol, 130 minutes from sucrose, 140 minutes from lactose, and 145 minutes from maltose.

COMMENT

The microtechnique yields results that are as reliable as those obtained with the usual macrotechniques. It not only yields quicker results but its use also results in a considerable saving in time and materials. The stock basal medium may be sterilized and stored in the refrigerator. Likewise, 20 per cent solutions

of the various fermentable substances may be sterilized by filtration and stored in the refrigerator, with proper precautions being taken against evaporation. When it is desired to test cultures, the fermentable substances and basal medium may be mixed in the proper proportions and the tests may be performed immediately. Only precautions to prevent excessive contamination in the process are necessary.

The microtechnique is usable under a variety of conditions. The length of the incubation period depends upon these conditions. The most important condition is the type and size of inoculum. The quickest results are obtained with heavy inoculums with logarithmic growth phase cultures that have been grown on a rich medium. On the other hand, reliable results can be obtained with single colonies from primary isolation plates. While the incubation period required in the microtechnique in the latter case is longer, the results are obtained much more quickly than if it were necessary to grow secondary cultures before the microtechnique tests were performed.

SUMMARY

A quick microtechnique for the demonstration of fermenting abilities of microorganisms has been described. It has proved to give reliable results with members of the *Euteroacteriaceae*. No tests have been run on other cultures.

Heavy inoculations are made into 0.15 ml quantities of medium in 5 by 50 mm tubes which have been preheated to 37° C. A beef heart infusion medium containing indicator is used as the basal medium. To it is added a sufficient quantity of sterile (filtered) 20 per cent solution of the fermentable substance to be tested to produce a 5 per cent solution in the final medium. The inoculated medium is capped with a 3 mm layer of a melted 1 per cent agar solution. The tubes are incubated at 37° C. Gas production is evinced by the collection of bubbles below the agar cap. Incubation periods of from 10 minutes to 12 hours, depending upon the size of inoculum and other factors, have been found to be necessary.

A TEST OF THE COAGULATION TIME OF BLOOD HEPARINIZED IN VITRO, STUDIES OF NORMAL SUBJECTS AND OF PATIENTS WITH INTRAVASCULAR THROMBOSIS

EDWARD E. ROSENBAUM, M.D.,* AND NELSON W. BARKER, M.D.†
ROCHESTER, MINN.

IT IS known that the addition of a specific amount of heparin to a specific amount of human blood may produce a variable increase of the coagulation time among different individuals. This principle has been applied by others in an attempt to develop a test which might be of value as an indication of increased coagulability of the blood in patients who have or may have thrombosis.

In 1943 de Takats and Gilbert¹ described a heparin tolerance test. They injected 10 mg. of heparin intravenously and determined the coagulation time of capillary blood drawn into capillary tubes before and at ten minute intervals after injection until the coagulation time returned to preinjection levels. With this test de Takats² noted that little or no increase of coagulation time occurred in patients who had undergone major surgical procedures or who had had coronary thrombosis, venous thrombosis, arterial embolism, or thrombo-angitis obliterans, while a definite increase occurred in normal persons. Although they do not detract from the importance of the principle involved, there are certain theoretic objections to the technique which was used, namely the method of testing the coagulation time that de Takats and Gilbert used is not generally considered to be as accurate and reproducible as other methods, the differences between the maximal coagulation times in normal persons and those with thrombosis were of the order of only a few minutes and possibly within the range of error of the method (Meyer),³ and tests were done at room temperature.

Waugh and Ruddick⁴ in 1944 described a test of coagulation time of blood heparinized in vitro. Their method consisted of adding 1 c.c. of venous blood to each of a series of test tubes in which there were increasing amounts of heparin from 1 unit (0.009 mg.) to 7 units (0.063 mg.). The chief practical objections to this method are that it is time consuming and that too many tubes requiring accurate mixtures of blood and heparin are necessary for each test. Waugh and Ruddick did their tests at room temperature.

Hagedorn⁵ repeated de Takats' heparin tolerance test but administered a larger amount of heparin, 25 mg., and determined coagulation times on venous blood (Lee-White method). He found that only two coagulation times were important, namely the one before injection and the one ten minutes after injection. Significant differences were found between the responses of normal

persons and the responses of a series of patients with intravascular thrombosis of various types. The differences seemed much greater than the possible error of the method of determining the coagulation time. Hagedorn also found a close correlation between the coagulation time of venous blood ten minutes after the intravenous injection of 25 mg of heparin and the coagulation time of 1 cc of venous blood added to a solution of 0.005 mg of heparin in vitro in each of a large series of both normal persons and patients with thrombosis. The chief objections to the Hagedorn method were that each test was time consuming and that tests were done at room temperature.

We wish to report the results of a coagulation test of venous blood heparinized in vitro in which we have attempted to increase the accuracy of the method and at the same time to simplify the technique so that only a minimal amount of time is expended in the performance of each test. In this test we have utilized the following equipment: a Barker coagulochronometer, a syringe adapted for accurately measuring and immediately mixing blood with a heparin saline solution, a box to maintain a constant air temperature of 37° C, Pyrex test tubes, venipuncture needles, and a solution of heparin.

The Barker coagulochronometer⁷ (Fig 1) is a machine that automatically records the coagulation time of whole blood or heparinized whole blood. The machine consists essentially of a photoelectric cell which operates a sensitive

relay, a light source for the cell, an electric motor which rotates at the rate of 1 revolution per minute, a horizontal shaft fitted with a test tube clamp, and an electric stop clock. Blood is placed in a test tube which is closed with a rubber finger cot or cork and the test tube is placed in the clamp where it is grasped by its midportion. As the test tube rotates, its top passes through the beam from the light source. As long as the blood is fluid, it runs to the lower end of the tube with each half-revolution. When the blood coagulates it adheres to the lower end of the tube, and when that end of the tube rotates upward to the vertical position, the blood clot interrupts the light beam and breaks the electrical circuit operating the motor and stop clock. Thus the coagulation time is automatically recorded. This machine is primarily a labor-saving device, since it eliminates frequent tipping of the tube by hand to determine the end point. Also it tips the tube at a constant rate and to a constant degree.

To insure direct and accurate mixing of the heparin and blood, a syringe was devised by one of us.⁸ This syringe, when fitted with a 21 gauge, $1\frac{1}{2}$ inch (3.8 cm) venipuncture needle, holds exactly 1 cc of heparin in a saline solution. Venipuncture was then performed with this syringe. By means of a spring release mechanism, exactly 1 cc of blood could be withdrawn into the heparin-saline solution. The blood and the heparin solution were mixed immediately in the syringe.

Whittaker⁹ demonstrated that heparinized blood must be kept at a constant temperature to obtain accurate coagulation times. In our early studies the coagulochronometer was kept in a cabinet in which the air temperature was maintained at 38° C. Later the midportion of each coagulochronometer was enclosed in transparent plastic and the air surrounding the test tube containing the blood was kept at 37° C by means of a heating element, thermostat and fan inside the closed space.

The solution of heparin was prepared by diluting Abbott's solution of heparin (10 mg per cubic centimeter) with 0.9 per cent solution of sodium chloride so that 1 cc contained 0.006 mg of heparin. This solution was prepared under sterile conditions and stored in vaccine bottles sealed with rubber diaphragms. All glassware was thoroughly cleaned and dried in drying ovens. When not in use, equipment was covered to avoid contamination with dust particles.

In performing a coagulation test with heparinized blood, a 21 gauge, $1\frac{1}{2}$ inch (3.8 cm), steel venipuncture needle was attached to the syringe and 1 cc of heparin-saline solution was drawn into the barrel of the syringe. A tourniquet was applied to the subject's arm and as soon as one of the cubital veins became distended it was punctured. A finger release spring on the syringe was then depressed and the plunger was pulled back until it stopped. In this way exactly 1 cc of whole blood was added directly to the 1 cc (0.006 mg of heparin) of heparin-saline solution. Care was taken that the venipuncture was neat and that no air entered the heparin-saline-blood mixture. The tourniquet was released and the needle was withdrawn from the vein. The needle was removed from the syringe and the contents of the syringe were gently poured

down the side of a Pyrex glass tube 8 mm in diameter and 100 mm long. The test tube was sealed with a rubber finger cot and gently inverted to mix its contents. The test tube was then placed in the test tube holder of the coagulochronometer and the time clock and the motor were started. When the blood coagulated, it broke the light beam thus stopping the motor and the clock. The coagulation time was read from the clock dial. Hereafter in this paper the time is referred to as the heparin coagulation time.

After the blood had been withdrawn from the vein there was a delay of about one minute before it could be placed in the machine and the time clock started. Since this delay was short and a relatively constant factor in all of our tests we do not feel that it constitutes a significant source of error in interpretation of results.

It was our experience in determining coagulation times with this technique that if coagulation did not occur within thirty minutes a satisfactory end point rarely occurred. It appeared that the constant rotation of the tube ultimately produced defibrination of the blood. Thus the results of all the tests could be roughly divided into two groups: those in which coagulation occurred in less than thirty minutes and those in which coagulation did not occur in thirty minutes.

To determine the variability of the heparin coagulation test repeated tests were done on each of sixteen subjects in whom the first heparin coagulation time was less than thirty minutes. In each subject three successive separate blood samples were drawn according to the described technique and each sample was placed in a different coagulochronometer. The results are shown in Table I. The variability measured as the standard deviation is shown

minutes. Subjects in whom the first determination of coagulation time was less than thirty

minutes. †No coagulation.

for each case. For the sixteen subjects the average standard deviation was 27 minutes, giving a significant variability of plus-minus 54 minutes*.

Five successive blood samples were drawn from five individuals in whom the first heparin coagulation time was more than thirty minutes. In none of the subsequent tests on these subjects was the heparin coagulation time less than thirty minutes.

The results of our studies of heparin coagulation time in control groups and in diseased states are shown in Table II. The second group in Table II consisted of patients who had been in bed from six to seventy days because of various diseases, but who did not have clinical evidence of intravascular thrombosis. In the cases of thromboangitis obliterans the disease was severe enough to require hospitalization. In each of the cases of arteriosclerosis obliterans the patient had been hospitalized because of ischemic ulcers or gangrene, but in no case had there been a recent arterial occlusion.

TABLE II DISTRIBUTION OF HEPARIN COAGULATION TIME IN VARIOUS CONDITIONS

DIAGNOSIS	TOTAL INDI- VIDUALS TESTED	HEPARIN COAGULATION TIME (MIN)							
		30 or longer		20-29		10-19		LESS THAN 10	
		NUMBER	PER CENT	NUMBER	PER CENT	NUMBER	PER CENT	NUMBER	PER CENT
Normal ambulatory subjects	50	41	82	2	4	7	14	0	
Bed patients without thrombosis	50	39	78	4	8	7	14	0	
Thromboangitis obliterans	14	8	57	2	14	4	29	0	
Arteriosclerosis obliterans	20	8	40	3	15	9	45	0	
Recent venous thrombosis or pulmonary embolism	19	2	11	5	26	2	11	10	51
Acute peripheral arterial occlusion	3	1	33	0	0	0	0	2	67

In each case of thrombophlebitis or pulmonary embolism in Table II, the diagnosis was definitely established clinically and blood samples were drawn within one to seven days after the clinical onset of thrombosis. Fifty-two per cent of these patients had coagulation times less than ten minutes, this rapid coagulation time was not observed in any of the control subjects whom we studied.

We also had an opportunity to study three patients with acute arterial occlusion in the extremities shortly after the occlusion occurred. In one patient the heparin coagulation time was thirty minutes or more, but in two the time was less than ten minutes.

SUMMARY

We have described a technique for the determination of the coagulation time of 1 cc of venous blood mixed with 1 cc of 0.9 per cent solution of sodium chloride containing 0.006 mg of heparin. The technique utilized a

*Plus-minus 2 times the standard deviation is a generally accepted range for statistically significant variation.

coagulochronometer (a machine for automatically recording the end point on a stop clock) and a syringe which was specially devised to permit first the withdrawal of exactly 1 cc of the heparin saline solution from a bottle and then of exactly 1 cc of blood from a vein into the heparin saline solution. All tests were done in an environmental temperature of 37 C.

Coagulation times by this method were less than thirty minutes in only 18 per cent of fifty normal ambulatory subjects and in 22 per cent of fifty bed patients without evidence of thrombosis. Coagulation times were less than thirty minutes in 53 per cent of thirty-four patients with chronic occlusive arterial disease of the extremities (thromboangitis obliterans or arteriosclerosis obliterans). Coagulation times were less than thirty minutes in 89 per cent and less than ten minutes in 52 per cent of nineteen patients with recent clinical venous thrombosis or pulmonary embolism. No coagulation times were less than ten minutes in any of the control subjects.

A CAGE WHICH LIMITS THE ACTIVITY OF RATS

JESSE L BOLLMAN, M D

ROCHESTER, MINN

WITH THE TECHNICAL ASSISTANCE OF EMERY VAN HOOK

THE cage shown in Fig 1 was developed to restrain a rat during periods of days while an indwelling tube was in place. It has proved very useful in collecting urine through an indwelling cystostomy tube, for continuous or intermittent injection through a small plastic tube inserted into a vein, for collection of lymph from the thoracic duct, intestine, or liver over periods of days through a small indwelling plastic tube in a lymphatic vessel, and for other procedures

Fig 1—The assembled cage.

The cage is made of Lucite $\frac{3}{8}$ inch thick, which may be worked with ordinary tools. The endpieces are 3 by 6 inches and the hole in each piece, which is $\frac{5}{8}$ inch in diameter, accommodates a drinking fountain tube or the tail of the rat. Fourteen steel rods, $6\frac{1}{2}$ inches long and $\frac{1}{8}$ inch in diameter, set approximately $\frac{1}{2}$ inch apart, constitute the floor and sides of the cage. These fit into slots drilled in one endpiece. Holes in corresponding positions in the other endpiece are drilled through and threaded to accommodate small brass screws. The enclosed space, $1\frac{3}{4}$ inches wide and $1\frac{3}{4}$ inches high, accommodates a rat which weighs 200 grams. Additional holes and slots may be made in the endpieces so that the rods may be placed to fit larger or smaller rats. The food cup, which is placed under an opening in the floor, has been satisfactory. To move a rat in or out of the cage it is necessary only to remove the screws at the ends of two or three rods and slide the rods through the openings.

TECHNIQUES FOR THE COLLECTION OF LYMPH FROM THE LIVER SMALL INTESTINE, OR THORACIC DUCT OF THE RAT

JESSE L. BOLLMAN, M.D.,* JAMES C. CAIN, M.D.,† AND
JOHN H. GRINDLAY, M.D.*
ROCHESTER, MINN.

WITH THE TECHNICAL ASSISTANCE OF CLERY VAN HOOK

THE following techniques for collection of lymph in the rat have been very satisfactory for periods of two or three days for lymph from the liver and for periods up to ten days for lymph from the intestine or from the thoracic duct. These methods have been useful in the study of lymph from the standpoint of the substances exchanged from the plasma to the lymph and of the materials contributed to the lymph from the intestine in the course of digestion and absorption of various foods.

Cannulation of the lymphatics of the liver is accomplished in rats weighing 150 to 300 grams. The rats are anesthetized with ether. Through a midline incision the liver is reflected upward to the right and the stomach and duodenum are reflected to the left, thus exposes the hepatogastric and hepatoduodenal ligaments. Evans blue dye, 0.1 ml. of a 0.5 per cent solution is injected through a fine hypodermic needle into the liver. Within a minute blue lymph may be seen in the lymphatics passing through the hepatogastric ligament. After the worker has acquired a little experience the clear lymphatics of the liver are easily recognized and the injection of dye is no longer necessary.

With the use of dissecting glasses, a blunt dissection with curved mosquito forceps proved the most practical method for isolation of the lymphatics. The inferior vena cava is dissected free above the right renal vein and a sharp 13 gauge needle is passed under the vena cava in line with the lymphatic vessel of the liver and through the abdominal wall. A plastic tube Transflex, 1 or 1.5 mm. in diameter with beveled ends, is filled with a dilute solution of heparin and passed through the needle to the outside. The needle is then removed. As much of the lymphatic as is exposed, usually 3 to 5 mm. is dissected free and ligated as far distally as possible. A small longitudinal opening is made in the lymphatic with the cutting edge of a 27 gauge hypodermic needle. One of the beveled tips of the plastic tubing is then passed into the lymphatic as far as possible and tied firmly in place (Fig. 1). A second ligature is placed near the vena cava so that the tubing is held in line with the direction of the lymphatic. Any accessory lymphatics in this region may be included in the ligature and since they anastomose freely, their flow is diverted to the cannulated lymphatic. Occasionally a small lymphatic from the duodenum may deliver cloudy lymph to the lymphatic vessel in the liver; this can be prevented by ligation of the small

lymphatic connection In the rat which has been fed a diet containing fat, the lymph from the liver remains clear and contamination with intestinal lymph is easily recognized

The lymph begins to flow immediately through the tubes, and after the incision is repaired the animal is placed in the cage described in another paper.¹ The lymph is collected in a graduated centrifuge tube from the plastic tube, the free end of which is passed through a small opening in a rubber cap on the centrifuge tube The plastic tube acts as a siphon and delivers the lymph best at 5 to 10 cm below the level of the rat

Fig 1—Structures involved in cannulation of a lymphatic of the liver and of an intestinal lymphatic.

Cannulation of the intestinal lymphatic which drains most of the small intestine is accomplished in a manner similar to that just described In the rat which has been fed a meal that contains fat the intestinal lymphatics are easily recognized because they appear in the lower portion of the hepatoduodenal ligament Evans blue dye injected into the substance of the intestine also stains the intestinal lymph blue There usually are accessory intestinal lymphatics which need to be ligated so that all the intestinal lymph may be collected through the main channel

Cannulation of the thoracic duct is accomplished in the etherized rat through an incision just distal to the last rib, extending from the midline anteriorly to the medial border of the left quadratus lumborum muscle posteriorly (Fig 2) A small gauze pack, placed in such a way that it pushes the stomach, liver, and intestines back and to the right, exposes the left portion of the dia

phragm, the aorta, and the left adrenal gland and kidney. A self containing mastoid retractor is used to retract the kidney distally and to hold the incision open. With the use of dissecting glasses a small opening is made in the peritoneum over the quadratus lumborum approximately 0.5 cm cephalad to the superior suprarenal artery. The vein and peritoneum are dissected superi-

Fig. —Method of cannulation of the thoracic duct

cially and retracted to the right until the aorta is exposed. The aorta in this region is freed of attached tissue until the left subcostal artery is exposed. The thoracic duct is visible just posterior to the aorta. It is 1 to 2 mm in diameter and is embedded in loose connective tissue and fat. The thoracic duct is exposed for a length of 5 to 8 mm by gentle blunt dissection, and a ligature is passed around it at the upper end of the exposed portion just caudad to the subcostal artery. A second ligature is placed 3 to 5 mm caudad to the first. A sharp 13 gauge needle is passed through the abdomen at approximately the level of the xiphoid process and the beveled plastic tubes 1.5 mm in diameter, which contain

a dilute solution of heparin, are threaded through to the site of cannulation. A small longitudinal opening is made in the left anterior surface of the thoracic duct with the cutting edge of a 27 gauge hypodermic needle. This opening may be enlarged with a probe. A beveled end of the plastic tube is then slipped gently into the duct for 5 to 10 mm and tied firmly in place with the second ligature. The first ligature is tightened about the cannula and the ends of both ligatures are tied together for further security. The tube is arranged so that it will lie relatively straight in the duct and yet will curve along the diaphragm before it passes through the abdominal wall. The gauze pack is removed, the viscera are replaced in proper position, and the incision is closed.

After operation the rats are placed in cages constructed according to the description previously mentioned. These cages are small in order to prevent the rat from turning around, but they do permit some forward and backward movement. The volume of lymph obtained varies somewhat with the dietary and fluid balance of the animal. For normal rats which weigh 200 grams and receive a mixed diet and water as desired, approximately 5 cc of clear hepatic lymph are collected each twenty-four hours for two or three days, when dislodgment or clotting within the cannula terminates the flow of lymph. In similar rats under similar conditions approximately 20 cc of intestinal lymph are collected every twenty-four hours and the flow of lymph is usually continuous up to about ten days. From the thoracic duct approximately 25 cc of lymph are collected each twenty-four hours for periods up to ten or more days. This figure is slightly greater than that reported by Reinhardt² for nonfasting adult rats whose thoracic ducts were cannulated by a different approach while they were under the effects of sodium pentobarbital anesthesia.

STUDIES ON Rh ANTIBODIES

ANALYSIS OF A ZONE PHENOMENON IN AN Rh ANTISERUM BY SPLITTING THE SERUM INTO TWO FRACTIONS BY MEANS OF DIALYSIS

ERNEST WITEBSKY, M D, AND JAMES F MOHN, M D

BUFFALO N Y

¹ For eighteen hours against large volumes of freshly distilled water, resulting in the division of serum into two fractions the precipitate and the supernatant, has been applied to the study of Rh antisera as reported in a previous communication¹. The precipitate consisting mostly of globulins which are soluble in physiologic saline solution contains the major portion of the complete (saline) Rh agglutinins. The 'supernatant fraction' is a mixture composed of the albumin and a certain amount of the globulins. In this fraction are found anti Rh antibodies of the incomplete (albumin) variety. The method is of certain practical interest in that rather potent anti Rh testing reagents can be prepared from sera containing complete (saline) Rh agglutinins of such weak titer that they could not be used for diagnostic purposes. This is accomplished by dissolving the precipitate in a relatively small volume of saline solution. However, the agglutinating power of the 'globulin fraction' can be explained not only by concentration of the complete (saline) Rh agglutinins proper but also partly by their separation from the Rh antibodies of the incomplete (albumin) variety which tend to 'block' or suppress the saline agglutinins as long as the former also are present. Herein lies the theoretic interest in this procedure for it seems to prove that the two varieties of Rh antibodies occur in different serum fractions.

Since the original report was made a large number of additional anti Rh sera have been examined by this method or a slightly modified adaptation of it. Many sera have shown principally the same results when subjected to dialysis. Considering that the method is as crude as it is simple, it was to be expected that not all Rh antisera would follow the same pattern. One serum which was of special interest because it seemed to differ from the regular behavior is the subject of the investigations to be reported in this and the two following communications. It was obtained from an Rh negative patient who received multiple transfusions of whole blood, the majority of which most probably were Rh positive, stimulating the production of Rh antibodies. A brief case history of this patient follows below.

Mr. Rea had seven hospital admissions between February 1937 and his death in February, 1946. He suffered primarily from chronic ulcerative colitis which was treated initially by ileostomy and finally by colectomy. During his first six stays in the hospital he received a total of 4,000 cc of citrated, whole blood compatible as to the blood group but unknown

From the Department of Bacteriology and Immunology, University of Buffalo School of Medicine and the Laboratories of The Buffalo General Hospital.

The findings reported in this and the following communications were presented during a meeting in Washington D C on Oct. 9 and 21 1947 convened at the request of the Surgeon General of the United States Public Health Service for a discussion on the nomenclature of Rh typing serums.

Received for publication Sept. 7 1948

as to the Rh factor. At the time of his final entrance into the hospital to undergo a total colectomy, he received in all 3,000 c.c. of citrated, whole blood belonging to his blood group but irrespective of the Rh type of the various bloods. The last 500 c.c. produced a severe hemolytic transfusion reaction. The analysis of the transfusion reaction carried out in our laboratory revealed the fact that the patient was an Rh negative individual whose serum contained an Rh antibody. A large quantity of blood was collected from this patient immediately after his decease. Examination of the serum obtained from this specimen showed an Rh antibody of the complete (saline) variety of only weak titer but one of the (albumin) variety of high titer. However, in no dilution of the patient's serum, agglutination of Rh positive cells greater than 2 plus macroscopically in the initial investigations carried out. The relatively weak degree of agglutination excluded the use of this serum for practical purposes as a diagnostic reagent. Accordingly, it was decided to dialyze a sample of it.

Two fractions were obtained by dialyzing 100 c.c. amounts of this serum for eighteen hours against two changes of 12 liters each of freshly distilled water in the refrigerator at approximately 4° C. The precipitate, to be referred to as the "globulin fraction," was separated by centrifugation from the remaining dialysate, to be referred to as the "supernatant fraction." The "globulin fraction" was dissolved in 10 c.c. of 0.9 per cent saline solution corresponding to one tenth the amount of the original serum specimen (a ten times concentration) and lyophilized in small ampules containing 10 c.c. each. When needed, they were dissolved by the addition of 10 c.c. of distilled water. The salt free "supernatant fraction" was also lyophilized and when needed was dissolved in physiologic saline solution. The experiments recorded in this paper all refer to the two serum fractions obtained in this manner.

In order to compare the relative distribution of the complete (saline) and incomplete (albumin) Rh antibodies in the two serum fractions with that in the native (untreated) serum, the first experiment was carried out in two parts. In Part I saline was used as the medium for preparing the dilutions of the serum and its fractions and for suspending the Rh positive test cells, while in Part II, undiluted, normal, adult, human serum of Group O was used as a diluent. Experiment I itself was carried out in the following manner.

Decreasing amounts of native serum (Ree) and its two fractions, volume 0.05 c.c., were mixed with 0.05 c.c. of a 2 per cent suspension of homozygous Rh₁ (CDe/Ce) cells belonging to blood Group O. The tubes were shaken thoroughly. After standing for one hour at room temperature they were centrifuged at approximately 1,500 revolutions per minute for two minutes and read macroscopically for agglutination as recorded in Table I.

This experiment shows that the complete (saline) Rh antibodies, which were very weak from the start, are somewhat concentrated in the "globulin fraction" corresponding to previous experiences. The "supernatant fraction" does not contain any complete (saline) anti-Rh agglutinins. When saline is replaced as a diluent by undiluted, normal, adult, human serum, incomplete (albumin) Rh agglutinins of considerable titer become apparent in the native serum. In this experiment, however, the degree of agglutination of Rh-positive test cells does not exceed the 2-plus stage in any of the dilutions tested. A zone phenomenon in the middle of the titration can be recognized. In contrast to the native serum, the "globulin fraction" produces a 4-plus agglutination of the Rh positive cells which is stronger than might be expected even if it is realized that this fraction corresponds to a ten times concentration of the original native serum. This "globulin fraction" also differs from "globulin fractions" previously described inasmuch as it contains Rh antibodies of the incomplete (albumin) variety reacting much stronger if undiluted serum is used as a diluent instead of saline solution.

The second fraction, "the supernatant," reveals a prozone phenomenon which is absent both in the native serum and in the "globulin fraction." On:

TABLE I AGGLUTINATION OF RH POSITIVE GROUP O CELLS BY SERUM (REE) AND ITS TWO FRACTIONS (GLOBULIN AND SUPERNATANT)

could readily visualize how the combined action of the two separate serum fractions could result in the type of agglutination that is shown by the native serum

Inasmuch as the experiment shown in Table I did not reach the end point of agglutination and because of the zone phenomenon observed a second experiment was carried out as follows

Decreasing amounts of the native serum (Ree) and its two fractions respectively, volume 0.05 cc were mixed with 0.05 cc of a 2 per cent suspension of homozygous Rh (CDe/Ce) Group O cells. The mixtures were allowed to remain for one hour at room temperature and then were spun down. The resulting agglutinations as read macroscopically are shown in Table II

All dilutions made with undiluted normal adult human serum of Group O

Experiment II again demonstrates the fact that the native serum upon titration exhibits a zone phenomenon most obviously in dilutions of 1/16 or 1/32, reaching an end point titer of approximately 260,000*. The "globulin fraction" reveals the presence of an incomplete (albumin) variety of Rh antibody of considerable strength decreasing in potency in a straight line with an end point of approximately 1/500,000* without showing any zone phenomenon. No agglutination occurs in the undiluted "supernatant fraction." As this fraction is diluted further an incomplete (albumin) anti-Rh antibody of increasing strength becomes apparent until a dilution of 1/512 is reached, whereafter it decreases, reaching an end point titer of approximately 1/8,000*.

The preceding experiments focused attention on the peculiar behavior of the "supernatant fraction" when titrated in undiluted, normal, adult, human serum. Was the prozone phenomenon due to surplus inhibition or to the activity of an antibody truly blocking in nature? When Wiener² first described his Rh "blocking antibody" ("incomplete" Rh antibody of Race³), he demonstrated its presence by its "blocking" effect on the Rh saline agglutinin (complete Rh antibody). However, experiments by Diamond and associates^{4,5} and Wiener¹ revealed that the so-called "blocking" antibody did not "block" at all if as a diluent saline solution were replaced by 20 per cent bovine albumin solution or undiluted human serum. Use of these latter substances as diluents resulted in agglutination of Rh-positive cells treated with such a "blocking" or "incomplete" antibody. In the case under discussion, undiluted, normal, adult, human serum was used as a diluent and still a prozone phenomenon was observed.

The blocking effect of the "supernatant fraction" was tested in Experiment III following a similar order of experiment as used in an earlier communication¹. The cell suspension and the dilutions of the "supernatant fraction" were all made in undiluted human serum instead of in physiologic saline solution. The experiment itself was carried out thusly:

Decreasing amounts of (A) "the supernatant fraction" of serum (Ree) and (B) the "supernatant fraction" of a normal, adult serum, used in this experiment as a control, volume 0.15 c.c., were mixed with 0.05 c.c. of a 6 per cent suspension of homozygous Rh₊ (CDe/Ce) cells belonging to blood Group O. The experiment was set up in duplicate (Part I and Part II). After incubation for one hour at room temperature, the following anti-Rh sera were added to each tube in Part I, 0.05 c.c. of undiluted "globulin fraction" of serum (Ree) to each tube in Part II, 0.05 c.c. of undiluted anti-D (Rh₀) serum (Dad) containing an Rh antibody of the incomplete (albumin) variety. The tubes after being shaken well were kept for an additional hour at room temperature, then centrifuged and read macroscopically for agglutination. The results obtained are recorded in Table III.

It can be seen that the "supernatant fraction" of serum (Ree) does indeed inhibit or block its own "globulin fraction," thus preventing the "globulin fraction" from agglutinating the Rh-positive test cells. It also prevents the agglutination of Rh-positive cells by anti-Rh agglutinins of the incomplete (albumin) variety contained in serum (Dad) (Part II) as compared with the "supernatant fraction" of the normal serum used as a control.

In Experiment III, decreasing amounts of the "supernatant fraction" showing the blocking phenomenon were mixed with constant amounts of the "globulin

*Inasmuch as pipettes were not changed with each dilution these figures should not be taken as absolute values.

fraction' and with another anti Rh serum containing incomplete (albumin) Rh antibodies. The next experiment to be reported reveals the blocking effect of this "supernatant fraction" of serum (Ree) when it is added in a constant amount to decreasing amounts of its own globulin fraction' and its own supernatant fraction". The experiment was performed as follows

Decreasing amounts of (A) the "globulin fraction" obtained from anti Rh serum (Ree) and (B) the "supernatant fraction" obtained from anti Rh serum (Ree) volume 0.05 cc, were mixed in Part I with 0.1 cc of undiluted supernatant fraction of serum (Ree), and in Part II with 0.1 cc of undiluted 'supernatant fraction' of a normal serum. After the tubes were shaken, 0.05 cc of a 5 per cent suspension of Rh (cDE/c) Group O cells was added to each. The tubes after remaining one hour at room temperature were centrifuged at 1500 revolutions per minute for two minutes; the resultant agglutinations were read macroscopically.

23 0	-	-	-	-
24 0 + 0.1 cc serum diluent	-	-	-	-

All dilutions made with undiluted normal adult human serum of Group O

and recorded in Table IV. In this experiment all dilutions and cell suspensions were prepared with undiluted, normal, adult, human serum of Group O.

When a constant amount of the undiluted "supernatant fraction" of Rh antiserum (Ree) is added to decreasing amounts of its own "globulin fraction," a marked suppression of the agglutination of the Rh-positive test cells results, reducing the titer of its own "globulin fraction" from 32,000 to 16. Furthermore, the undiluted "supernatant fraction" of serum (Ree) when added in constant amount to decreasing amounts of the same "supernatant fraction" of serum (Ree) itself, completely suppresses and prevents the agglutination of the Rh-positive cells by the incomplete (albumin) Rh antibody contained in the greater dilutions of this "supernatant fraction." In contrast, the addition of the "supernatant fraction" of a normal serum fails to prevent the agglutination of the Rh-positive test cells by the "globulin fraction" and the "supernatant fraction" of serum (Ree).

In the experiments described thus far, the blocking effect of the "supernatant fraction" of the anti-Rh serum (Ree) was tested against its own "globulin fraction," which contains a very potent incomplete (albumin) Rh antibody, and against one additional anti-Rh serum (Dad) containing the same type of Rh antibodies but of lower titer. What effect would the "supernatant fraction" of serum (Ree) have on anti-Rh antibodies of the complete (saline) variety? To find the answer to this question, two anti-Rh sera with antibodies of the complete (saline) variety and an additional anti-Rh serum with antibodies of the incomplete (albumin) variety were tested in Experiment V. All of the dilutions and the cell suspension were made with undiluted, normal, adult, human serum of Group O. This experiment was carried out in the following manner:

Decreasing amounts of (1) anti Rh globulin (Dib), containing Rh antibodies of the complete (saline) variety, (2) anti Rh serum (And), containing Rh antibodies of the complete (saline) variety, and (3) anti Rh serum (Dad), containing Rh antibodies of the incomplete (albumin) variety, volume 0.05 cc, were mixed in Part I with 0.1 cc of undiluted "supernatant fraction" of serum (Ree) and in Part II with 0.1 cc of undiluted "supernatant fraction" of a normal serum. Each tube received 0.05 cc of a 5 per cent suspension of Rh (cDE/c) cells belonging to the blood Group O. Following the addition of the test cells the mixtures were incubated for one hour at room temperature and were then centrifuged. The resulting agglutinations are recorded in Table V.

TABLE V. BLOCKING EFFECT OF "SUPERNATANT FRACTION" OF SERUM (REE) ON AGGLUTINATION OF RH POSITIVE GROUP O CELLS BY THREE ANTI RH SERA

ANTI RH SERA	PART I SUPERNATANT FRACTION OF SERUM (REE)			PART II SUPERNATANT FRACTION OF NORMAL SERUM		
	A GLOBULIN (DIB)	B SERUM (AND)	C SERUM (DAD)	A GLOBULIN (DIB)	B SERUM (AND)	C SERUM (DAD)
1 Undiluted	—	—	—	++++	+++	++
2 1:2	—	—	—	++++	+++	+
3 1:4	—	—	—	+++	++	—
4 1:8	—	—	—	+++	+	—
5 1:16	—	—	—	++	+	—
6 1:32	—	—	—	+	—	—
7 1:64	—	—	—	+	—	—
8 1:128	—	—	—	+	—	—
9 1:256	—	—	—	—	—	—
10 0	—	—	—	—	—	—

- A Globulin (Dib) contains anti-Rh antibodies of the incomplete (albumin) variety
 B Serum (And) contains anti-Rh antibodies of the complete (saline) variety
 C Serum (Dad) contains anti-Rh antibodies of the incomplete (albumin) variety

It can be seen from this experiment that the 'supernatant fraction' of serum (Ree) completely suppresses the agglutination of Rh positive cells by anti Rh agglutinins irrespective of whether they are of the incomplete or the complete variety. The supernatant fraction prepared from a normal human serum does not prevent the agglutination of the Rh positive cells by any of the anti Rh sera tested.

DISCUSSION

Zone phenomena frequently have been seen upon quantitative titration of Rh antisera. Taylor, Race, Prior, and Ikin¹⁰ reported an anti Rh containing serum which when used undiluted caused according to their interpretation, the agglutination of cells classed as strongly positive reactors to Rh antibodies but failed to agglutinate weaker cells. Upon serial dilutions of this serum these weakly reacting cells also were agglutinated. The authors suggested at this time that the titration method should be applied to sera for the detection of Rh antibodies.

Attention was called by Levine¹¹ to the fact that prozone phenomena were occasionally observed in anti Rh sera. He warned that such sera should not be used for routine Rh typing. The same author with Waller¹ in additional experiments carried out on sera exhibiting prozones reported that this phenomenon could be explained by the fact that such sera contained a mixture of complete (saline) and incomplete (albumin) Rh agglutinins. The latter antibody acted as a 'blocking antibody' preventing the agglutination of Rh positive cells in the first few dilutions. By absorption with Rh positive cells this prozone could be eliminated, apparently due to the removal of the incomplete (albumin) type of Rh antibody.

After the investigations of various authors had shown that the 'blocking' antibody of Wiener, or the incomplete antibody of Race could be demonstrated directly when undiluted human serum or 20 per cent bovine albumin replaced saline solution as the diluent Levine¹² reported that quantitative studies on the 'direct reaction' of this so called 'blocking' antibody revealed the presence of a prozone phenomenon in certain instances. He raised the question whether there were not two varieties of 'blocking' antibodies.

Hattersley and Fawcett¹⁴ reported three instances of Rh antisera showing prozones when titrated in undiluted human serum and tested against Rh positive cells suspended in 30 per cent bovine albumin. The prozones observed by them did not appear at room temperature but only following incubation of the serum cell mixtures for one hour at 37° C. This prozone occurred only with cells of the subtype Rh₀ but not with Rh' or Rh'' cells. If the tubes were centrifuged immediately after the titration was completed the prozone phenomenon failed to appear. As a result of this observation Hattersley¹⁵ suggested a modification of the technique of routine Rh typing using the readily available Rh antisera containing Rh agglutinins of the incomplete (albumin) variety and centrifuging at high speed without preliminary incubation in order to eliminate falsely negative reactions as a result of the prozone phenomenon. It is interesting to note that the prozone phenomenon increased in Hattersley and Fawcett's case 3 following stimulation of the patient with small injections of Rh positive blood belonging to the subtype Rh₁.

SUMMARY AND CONCLUSIONS

The method of splitting anti-Rh sera into two fractions by dialysis, namely the precipitate (globulins) and the supernatant (mixture of albumin and globulins), has been applied to the serum of an Rh-negative patient (Ree) who produced Rh antibodies following multiple transfusions of Rh-positive blood over a period of several years. The comparison of the untreated serum with its two fractions led to the following observations:

1 The native, untreated serum when tested for Rh antibodies, using undiluted human serum as a diluent, contained Rh agglutinins of the incomplete (albumin) variety up to a titer of approximately 260,000. However, definite zones of agglutination became apparent upon quantitative titration.

2 Marked agglutination of Rh-positive cells decreasing in strength in a straight line upon dilution was produced by the "globulin fraction." No zone phenomenon was observed with this fraction.

3 The second fraction, the "supernatant," showed a strong prozone phenomenon in the first few dilutions. By "combining" the two fractions, the "globulin" and the "supernatant," the irregular zone phenomenon of the native, untreated serum can be understood.

4 The "supernatant fraction" of serum (Ree) blocks the agglutination of Rh-positive cells by both the complete (saline) and the incomplete (albumin) varieties of Rh antibodies. This is in contrast to the blocking effect of the incomplete (albumin) antibody which inhibited the agglutination of Rh-positive cells by the complete (saline) Rh antibody only but induced agglutination of Rh-positive cells by its own action when saline solution was replaced by undiluted normal serum or albumin solution.

STUDIES ON RH ANTIBODIES

II THE DEMONSTRATION OF A THIRD TYPE OF RH ANTIBODY WITH BLOCKING PROPERTIES

JAMES F. MOHN, M.D., and ERNEST WITFBSKY, M.D.
BUFFALO, N. Y.

THE preceding communication¹ described experiments carried out on an anti Rh serum obtained from an Rh negative patient who had received multiple transfusions of Rh positive blood. This serum showed a peculiar zone phenomenon upon quantitative titration. When divided into two fractions by dialysis, the precipitate (the globulin fraction) and the supernatant (the "supernatant fraction"), the globulin fraction produced agglutination of Rh positive cells decreasing in potency in a straight line following the serial dilutions without exhibiting a zone phenomenon. In contrast the supernatant fraction showed a definite prozone phenomenon which was not evident in the native serum itself.

Prozone phenomena have been encountered frequently during Rh antibody investigations as mentioned in the preceding paper.¹ The experiments to be reported in this second communication deal with the problem of whether the prozone phenomenon found in the "supernatant fraction" of serum (Ree) is due to a surplus inhibition (surplus of Rh antibodies) or is caused by the presence of a peculiar antibody exhibiting a blocking effect which in contrast to the "blocking" antibody described by Wiener,² manifests itself even when undiluted, normal, adult, human serum is used as a diluent.

Assuming that we are dealing with a true antibody effect and not a surplus inhibition, Rh positive cells treated with such an antibody should remain blocked although subjected to multiple washings with physiologic saline solution or undiluted normal, human serum. On the other hand if the zone phenomenon were due to a surplus of Rh antibodies multiple washings of the sensitized cells should result in a removal of this surplus of antibodies thus causing agglutination to occur. The experiments to be reported herein deal with this problem. From the technical point of view two different procedures were involved in each experiment: one, in which the Rh positive cells were treated with the "supernatant fraction" of serum (Ree) followed by a series of thorough washings of these blood cells, and the second, which consisted of the actual testing of the sensitized cells by means of the addition of anti Rh sera containing different varieties of Rh antibodies.

The first experiment well illustrates the principal procedures employed. It was performed in order to determine whether or not the supernatant frac-

Received for publication Sept. 1948.

tion" of serum (Ree) contained an antibody which would sensitize Rh positive cells and thus prevent their agglutination when subsequently mixed with anti Rh serum. Experiment I was carried out as follows:

I Method of Sensitization of Rh Positive Cells—

- 1 0.5 cc of a 10 per cent suspension of Rh₊ (cDE/c) cells belonging to blood Group O was added to each of ten tubes in two rows of five tubes each.
- 2 To Row (A), increasing dilutions (1) undiluted, (2) 1/3, (3) 1/9, (4) 1/27, and (5) 1/81 of the "supernatant fraction" of serum (Ree) were added in a volume of 1.5 cc per tube. A total volume of 2.0 cc was obtained in all tubes, the only difference being the amount of the "supernatant fraction" present in each tube.
- 3 The tubes were shaken well and kept for thirty minutes in the refrigerator at 4° C.
- 4 After centrifuging the tubes for ten minutes at 4,500 revolutions per minute, the supernatant fluids were aspirated and discarded.
- 5 The sediments, consisting of packed red blood cells, were washed thoroughly three times using 5.0 cc of ice cold 0.9 per cent saline solution per tube.
- 6 After the third washing all of the saline solution was removed as completely as possible by aspiration.
- 7 0.5 cc of undiluted, normal, adult, human serum was added to each tube and the sedimented cells were resuspended completely in the serum.
- 8 A parallel Row (B) was set up under identical experimental condition (tube 17), the only difference being that the "supernatant fraction" of a normal serum was used (control).

II Method of Testing the Sensitized Rh Positive Cells for Agglutination With Anti Rh Sera—0.05 cc of the cell suspensions was removed from each of the tubes of Row (A) and Row (B) and pipetted into a new series of small tubes. The experiment was carried out in duplicate. To each tube in Part I, 0.05 cc of undiluted anti D (Rh₀) serum containing Rh agglutinins of the complete (saline) variety was added, and to each tube in Part II, 0.05 cc of undiluted anti D (Rh₀) serum containing Rh agglutinins of the incomplete (albumin) variety was added. After being allowed to stand for thirty minutes at room temperature, the tubes were spun down for two minutes at 1,500 revolutions per minute. The resulting agglutinations are seen in Table I.

TABLE I AGGLUTINATION BY ANTI RH SERA OF RH POSITIVE CELLS TREATED WITH THE "SUPERNATANT FRACTION" OF SERUM (REE)

SUPERNATANT FRACTIONS	PART I ANTI D (RH ₀) AGGLUTININS COMPLETE (SALINE) VARIETY		PART II ANTI D (RH ₀) AGGLUTININS INCOMPLETE (ALBUMIN) VARIETY	
	A SERUM (REE)	B NORMAL SERUM	A SERUM (REE)	B NORMAL SERUM
1 Undiluted	—	++++	—	++++
2 1/3	—	++++	+	+++
3 1/9	—	++++	+	++
4 1/27	+	++++	++	++
5 1/81	++	++++	+++	+++

All dilutions made with undiluted normal adult human serum of Group O

- No agglutination
- ± Faint agglutination
- + Slight agglutination
- ++ Marked agglutination
- +++ Strong agglutination
- ++++ Very strong agglutination

*Physiologic saline solution was used for all of the dilutions and washing as previous experiments revealed that there was no difference in the outcome of the experiments irrespective of whether saline or undiluted normal adult human serum was used.

According to Experiment I Rh positive cells treated with the supernatant fraction of serum (Rce) fail to be agglutinated upon the addition of Rh antibodies of both the complete (saline) and the incomplete (albumin) variety depending upon the amount of the supernatant fraction of the serum (Rce) used for the sensitization of these cells. The complete (saline) type of Rh agglutinin seems to be blocked more easily than the incomplete (albumin) type. In contrast, the 'supernatant fraction' obtained from a normal adult human serum does not exhibit any blocking properties indicating the specificity of the effect observed.

The results of this experiment were corroborated in many others carried out in an identical or similar manner and seem to suggest that the prozone phenomenon observed in the supernatant fraction of serum (Rce) is due to a peculiar type of Rh antibody rather than to the presence of a surplus of Rh antibodies which should have been removed by the multiple washings.

The question arose whether the inhibition of agglutination shown in the first experiment could be reproduced with an Rh antibody of the known incomplete (albumin) variety previously described by Rice³ and Wiener⁴ or whether the blocking phenomenon was caused by a different third type of Rh antibody present in the 'supernatant fraction' of serum (Rce).

In an attempt to answer this problem an experiment was carried out on a qualitative basis comparing the supernatant fraction of serum (Rce) with the 'supernatant fraction' of anti Rh serum (Fis) known to contain Rh agglutinins of the incomplete (albumin) variety. Experiment II was performed as follows:

I Method of Sensitization of Rh Positive Cells.—

1. 0.5 cc of a 10 per cent suspension of heterozygous Rh (CDe/ce) cells belonging to blood Group O was added to each of three tubes.
2. 0.5 cc of undiluted supernatant fractions was added to each tube as follows:
 Tube (A) 'Supernatant fraction of serum (Rce)
 Tube (B) 'Supernatant fraction of serum (Fis)
 Tube (C) Supernatant fraction of a normal adult human serum (control)
3. The three tubes were shaken well and kept for thirty minutes in the refrigerator at 4°C. Following this incubation period examination of the tubes revealed agglutination in tube (B) with the supernatant fraction of serum (Fis) known to contain incomplete (albumin) Rh agglutinins. No visible agglutination was detectable in the other two tubes (A) and (C).
4. The tubes were centrifuged for ten minutes at 4500 revolutions per minute and the supernatants were aspirated andaved for further testing as will be described in a later experiment (Experiment III).
5. The cell sediments were washed thoroughly three times using 5.0 cc of ice cold physiologic saline solution for each tube. When saline solution was added the first time the packed cells in tubes (A) and (C) completely dispersed showing no agglutination. However the cells in tube (B) which had been treated with the incomplete (albumin) Rh agglutinins of the 'supernatant fraction' of serum (Fis), again showed definite agglutination. This clumping was completely broken up by vigorous shaking and inverting of the tube. Some agglutination still occurred in tube (B) following the second washing but to a much lesser degree than at the time of the first washing. When the cells were washed a third time no visible agglutination was noticeable.

- 6 After the third washing and centrifugation the saline solution was removed as thoroughly as possible by aspiration
- 7 0.5 cc of undiluted, normal, adult, human serum then was added to each of the three tubes and the packed, sedimented cells were resuspended completely

II *Method of Testing the Sensitized Rh-Positive Cells for Agglutination With Anti Rh Sera*—To 0.05 cc of each of the three sensitized cell suspensions pipetted into three rows of three small tubes each were added in Row (1), 0.05 cc undiluted anti D (Rh_0) serum containing Rh agglutinins of the complete (saline) variety, in Row (2), 0.05 cc undiluted anti D (Rh_0) serum containing Rh agglutinins of the incomplete (albumin) variety, and in Row (3), 0.05 cc of undiluted, normal, adult, human serum. After standing for one hour at room temperature, the tubes were centrifuged for two minutes at 1,500 revolutions per minute and read macroscopically for agglutination. The results are seen in Table II.

TABLE II AGGLUTINATION BY ANTI RH SERA OF RH POSITIVE CELLS TREATED WITH THE "SUPERNATANT FRACTIONS" OF SERUM (REE), SERUM (FIS), AND A NORMAL SERUM

	SUPERNATANT FRACTIONS		
	A SERUM (REE)	B SERUM (FIS)	C NORMAL SERUM
1 Anti D (Rh_0) agglutinins (complete)	—	++++	++++
2 Anti D (Rh_0) agglutinins (incomplete)	—	++++	++++
3 Normal, adult, human serum	—	±	—

All dilutions made with undiluted, normal adult human serum of Group O

The "supernatant fraction" of serum (Ree) completely suppresses agglutination of the test cells. In contrast, the "supernatant fraction" of a serum containing Rh antibodies of the incomplete (albumin) variety fails to inhibit the agglutination of Rh-positive cells upon the subsequent addition of Rh agglutinins of either the complete (saline) or the incomplete (albumin) variety, behaving exactly as the "supernatant fraction" of the normal serum.

Attention should be called to the fact that Rh-positive cells treated with a "supernatant fraction" containing incomplete (albumin) Rh antibodies were only slightly agglutinated, if at all, following their resuspension in undiluted, normal, adult, human serum (3B). This observation suggests that the incomplete (albumin) type of Rh agglutinins can be removed from Rh positive cells by simple washing, a finding which will be discussed later in detail.

As mentioned, the supernatants obtained in step 4 during the preparation of the preceding experiment were kept for further study. They are nothing else but the absorbed "supernatant fractions" of the Rh antisera used in Experiment II. It was of interest to find out in what way the Rh agglutinin content of these sera was affected by treatment with Rh-positive cells.

Experiment III shows the influence of absorption upon the Rh antibody content of the "supernatant fraction" of the two anti-Rh sera. The titration were set up in two parts as follows:

Decreasing amounts of the "supernatant fractions" of sera (Ree) and (Fis) respectively, volume 0.05 cc, in Part I, before absorption, and in Part II, after absorption, were mixed each with 0.05 cc of a 2 per cent suspension of heterozygous Rh_1 (CD_1/c) Group O cells. The tubes were shaken thoroughly and allowed to stand for forty-five minutes at room temperature. They then were centrifuged and read macroscopically for agglutination as recorded in Table III. As a diluent for all the dilutions and the test cell suspension, undiluted, normal, adult, human serum of Group O was used.

TABLE III AGGLOUTINATION OF RH POSITIVE CELLS BY THE ' SUPERNATANT FRACTIONS' OF SERUM (REE) AND SERUM (FIS) BEFORE AND AFTER ABSORPTION

SUPERNATANT FRACTION	PART I BEFORE ABSORPTION		PART II AFTER ABSORPTION

12 0	-	-	-	-

All dilutions made with undiluted normal adult human serum of Group O

The comparison of the supernatant fractions of serum (Ree) and serum (Fis) respectively reveals an interesting contrast. Treatment of the supernatant fraction of serum (Ree) with Rh positive cells has resulted in a surprising increase in the degree of agglutination obtained rather than in a decrease as would be expected. On the other hand treatment of the supernatant fraction of serum (Fis) carried out under identical conditions has resulted in a considerable loss of the Rh antibody content. Apparently a blocking type of Rh antibody has been absorbed from the supernatant fraction of serum (Ree) allowing the incomplete (albumin) type of Rh antibody also present to act on the Rh positive test cells to a greater degree than before absorption. This paradoxical phenomenon seems to be explained best by the assumption of differences in the avidity of the various types of Rh antibodies for Rh positive cells.

That absorption of the supernatant fraction of serum (Ree) with Rh positive cells indeed increases rather than decreases its agglutinating potency under certain quantitative conditions is shown in the following Experiment IV

I Method of Absorption of Supernatant Fraction of Serum (Ree)*—

- 1 10 cc of the undiluted "supernatant fraction" of serum (Ree) was added to 10 cc of three washed packed heterozygous Rh (CDe/c) Group O cells, mixed and kept for thirty minutes in the refrigerator at 4°C.
- 2 Following centrifugation for ten minutes at 4500 revolutions per minute the supernatant fluid was aspirated, saved and labelled "Absorbed Fluid No 1". An aliquot was removed for testing purposes.
- 3 The remaining "Absorbed Fluid No 1" was reabsorbed with an equal volume of washed packed cells kept at 4°C and centrifuged; the supernatant was aspirated and labelled "Absorbed Fluid No 2".

II Quantitative Testing of the Absorbed Supernatant Fraction of Serum (Ree)—Decreasing amounts of (a) the supernatant fraction of serum (Ree) before absorption (b) after the first absorption ("Absorbed Fluid No 1") (c) after the second absorption ("Absorbed Fluid No 2") volume 0.05 cc were mixed with 0.05 cc of 12 per cent suspension of heterozygous Rh (CDe/c) Group O cells. Undiluted human serum was used as a

*For this experiment the lyophilized supernatant fraction of serum (Ree) was dissolved in undiluted normal adult human serum of Group A instead of in 0.9 per cent saline solution.

diluent throughout the experiment. After standing for forty five minutes at room temperature the tubes were centrifuged at 1,500 revolutions per minute for two minutes. The resulting agglutination as read macroscopically is recorded in Table IV.

TABLE IV AGGUTINATION OF RH POSITIVE CELLS BY THE "SUPERNATANT FRACTION" OF SERUM (REE) AND THE ABSORBED FLUIDS PREPARED FROM THIS FRACTION

17 1 65,536	-	-	-
18 0	-	-	-

All dilutions made with undiluted normal adult human serum of Group O

Treatment of the "supernatant fraction" of serum (Ree) with an equal volume of packed Rh-positive cells increases the degree of agglutination of Rh positive cells produced by this fraction. It also reduces the prozone. Upon further absorption, however, a decrease in agglutination of Rh positive cells occurs, suggesting that following the removal of the blocking variety of Rh agglutinins the incomplete (albumin) variety of Rh agglutinins is removed next.

In order to study the specificity of the blocking effect of the "supernatant fraction" of serum (Ree) upon the agglutination of Rh-positive cells, the following experiment was set up.

A 10 per cent suspension of homozygous Rh₁ (CDe/Ce) Group O cells was mixed with equal volumes of (1) undiluted, (2) 1 10 diluted, and (3) 1 100 diluted "supernatant fractions" respectively of (A) anti Rh serum (Ree), and (B) normal adult human serum. The washing and resuspending procedures were identical with those described in detail under Experiment I.

The blood cells treated in this way were tested for agglutination in the following manner.

To 0.05 cc of each of the sensitized cell suspensions was added in Part I, 0.05 cc of an undiluted anti D (Rh₀) serum, and in Part II, 0.05 cc of an undiluted anti C (Rh') serum. Both anti Rh sera contained Rh antibodies of the complete (saline) variety. The tubes were allowed to remain thirty minutes at room temperature, then were centrifuged and read macroscopically for agglutination as shown in Table V.

Homozygous Rh₁ (CDe/Ce) cells treated with the "supernatant fraction" of serum (Ree) fail to be agglutinated upon the addition of anti D (Rh₀) serum. However, the addition of anti-C (Rh'-70%) serum brings about agglutination without showing any trace of inhibition.

TABLE V AGGLUTINATION BY ANTI D (Rh) AND ANTI C (Rh) SERA OF Rh POSITIVE CELLS TREATED WITH THE "SUPERNATANT FRACTION OF SERUM (REE)

SUPERNATANT FRACTIONS	PART I ANTI D (Rh) SERUM		PART II ANTI C (Rh) SERUM	
	A SERUM (RBC)	B NORMAL SERUM	A SERUM (RBC)	B NORMAL SERUM
1 Undiluted	-	++++	++++	++++
2 1 10	-	++++	++++	++++
3 1 100	+	++++	++++	++++

All dilutions made with undiluted normal adult human serum of Group O

A similar type of experiment carried out with Rh₂ (cDE/c) cells using an anti E (Rh'') serum proved that agglutination of Rh cells by an anti E antibody was not inhibited by the supernatant fraction of serum (Ree). The blocking effect of the supernatant fraction of serum (Ree) therefore corresponds to the specificity of an anti D (Rh) antibody. These results parallel the findings obtained by Hattersley and Fawcett⁴ in their study of the prozone phenomena shown by several anti Rh sera.

DISCUSSION

The experiments described in this paper were designed to analyze the nature of the prozone phenomenon of the 'supernatant fraction' obtained by dialysis from a certain anti Rh serum (Ree). The question presented itself as to whether this prozone was caused by a surplus of Rh antibodies or was due to the presence of a new and different type of Rh antibody which inhibited rather than produced agglutination. Rh positive cells after being exposed to the 'supernatant fraction' of serum (Ree) in concentrations which gave the prozone effect should have become agglutinated following removal of an excess of Rh antibodies by multiple washings. Rh positive cells treated in this manner, however, did not only fail to become agglutinated when resuspended in saline solution or undiluted normal adult human serum but also could not be clumped any more by the addition of Rh antisera containing Rh antibodies of either the complete (saline) or the incomplete (albumin) varieties. It is difficult to avoid the conclusion that the prozone phenomenon under discussion must be caused by an Rh antibody of blocking character rather than by the presence of a surplus of Rh antibodies of the two known varieties (complete and incomplete).

Furthermore maximum agglutination of Rh positive cells (4 plus agglutination) should have occurred upon serial dilution of the 'supernatant fraction' of serum (Ree) provided the prozone phenomenon was due only to an excess of Rh antibodies and not to the presence of a particular blocking antibody. This fraction, however, never produced agglutination of the 4 plus strength yet 4 plus agglutination occurred following its absorption with Rh positive cells. The new type of Rh antibody herein described must therefore possess a greater avidity for the Rh antigen of the red blood cell than the incomplete (albumin) Rh antibody. This latter antibody in turn is evidenced by the experiments of Coombs and Ree⁵ and Levine and Waller⁶ has a greater avidity

for the Rh antigen than the complete (saline) Rh antibody. In other words, there is a difference in the speed of combination between the various types of Rh antibodies and the Rh antigen.

In addition to differences in the speed of union between Rh antigen and the different Rh antibodies, there seems also to be a difference in the strength of the Rh antigen-antibody combinations. Multiple washings with saline solution removed the incomplete (albumin) variety of Rh antibody from Rh positive cells in contrast to the new type of Rh antibody which remained attached to the cells, apparently not being influenced by the multiple washing procedure.

CONCLUSIONS

1 The prozone phenomenon observed in the "supernatant fraction" obtained by dialysis from an anti-Rh serum (Ree) was found to be due to a new (third) type of Rh antibody rather than to a surplus of Rh antibodies of known varieties.

2 This new type of Rh antibody, when mixed with Rh positive cells prevented their agglutination upon the subsequent addition of Rh antisera containing Rh agglutinins of both the complete (saline) and the incomplete (albumin) variety.

3 In contrast, the "supernatant fractions" obtained by dialysis from sera containing the incomplete (albumin) variety of Rh antibodies, as well as from normal sera, failed to reveal any inhibitory effect on the agglutination of Rh positive cells.

4 The third type of Rh antibody could not be removed from Rh positive cells by multiple washings with saline solution, in contrast to the incomplete (albumin) type of Rh antibody which can be eluted by a series of washings.

5 Absorption of the "supernatant fraction" of serum (Ree) with equal volumes of Rh-positive cells increased rather than decreased the agglutinating properties of this fraction. In contrast, the agglutinin titer of a "supernatant fraction" containing only the incomplete (albumin) type of Rh antibody was reduced materially by this treatment.

6 The third Rh antibody described was found to have anti D (Rh₀) specificity.

STUDIES ON RH ANTIBODIES

III ANALYSIS OF A ZONE PHENOMENON IN AN RH ANTISERUM SPLIT BY DIALYSIS INTO FOUR FRACTIONS

JAMES F MOHN M D AND ERNEST WITEBSKY M D
BUFFALO N Y

THE observations reported in the two preceding papers^{1, 2} dealt with the anti Rh serum (Ree) and its two fractions obtained by dialysis for eighteen hours following the method described previously.³ However the amount of precipitate which formed during this period varied for different sera. It was influenced by the character of the serum itself such as its lipid content and depended, to a certain extent at least upon the amount of distilled water used the number of changes of distilled water made during each dialysis period and other factors. Furthermore, after removal of the first precipitate which formed after eighteen hours additional precipitation occurred following continued dialysis. Assuming that precipitates formed during various stages of dialysis would also correspond to different globulin fractions of the serum then antibody content was examined. The method used constituted a further division of the original serum into four fractions (three globulin fractions and one supernatant fraction") in contrast to the previous dialysis technique which allowed the splitting of anti Rh sera into two fractions only (the "globulin fraction" and the "supernatant fraction"). This more refined method of dialysis of anti Rh sera revealed results which are the subject of this report.

TECHNIQUE

All of the dialysis experiments reported in this and in the previous communications were performed using the same type of dialysis membrane which was prepared by cutting a sufficient length of viscose tubing, using .7/32 inch ending of a size approximately 43 mm in diameter. A bag was made from the piece of tubing by folding one end upon it self several times and securing it tightly with twine. The tubing was opened by moistening it with distilled water, and was filled with distilled water testing for leakage by placing the contents of the bag under as great a tension as possible. The respective serum specimen to be examined which was stored frozen at -30° C was thawed at room temperature. Using a small glass funnel 100 cc of this serum were poured into the viscose tubing bag. The air was forced out of the membrane without appreciable loss of the serum and the open end of the bag was twisted tightly in order to put the serum under tension. This end then was secured firmly with twine. After weighting the bottom end of the dialyzing bag with a one hole rubber stopper, the outside was rinsed thoroughly with distilled water. The bag then was suspended from a glass stirring rod into a battery jar holding 12,000 cc of freshly distilled water precooled to 4° C by storage in the refrigerator for at least four hours prior to dialysis. Dialysis was allowed to continue in this first battery jar in the refrigerator at 4° C for six hours. After this period the dialyzing bag was transferred to a second battery jar also containing

Received for publication Sept. 1, 1948.

The viscose tubing consists of regenerated cellulose and is made commercially by the Visking Corporation Chicago Ill. It is obtainable from laboratory supply houses such as the Fisher Scientific Company, Pittsburgh Pa. or the Will Corporation Rochester N. Y.

12,000 cc of freshly distilled water precooled to 4° C, and dialysis was permitted to continue in the refrigerator for twelve hours. The total time period allotted for this first phase of dialysis was eighteen hours.

The bag then was inverted several times, resuspending completely the precipitate which had settled to the bottom, and the exterior of the membrane was rinsed with distilled water. The bottom of the bag was opened by severing the string and the contents were emptied into a large glass beaker.

Approximately half of the dialysate was transferred to a plastic centrifuge tube of 50 cc capacity and centrifuged in an angle centrifuge at 3,000 revolutions per minute for thirty minutes. The supernatant was decanted off and saved. The remaining half of the dialysate was added to the same centrifuge tube containing the sediment obtained in the previous run and spun down, thus collecting all of the precipitate in the one centrifuge tube. The supernatants were combined as "supernatant fraction" and saved for further dialysis. The tube containing the packed sediment was inverted on coarse filter paper and allowed to drain for thirty minutes at room temperature.

The precipitate recovered from the 100 cc of serum was dissolved in 10 cc of 0.9 per cent saline solution which was added in divided amounts. After each portion of saline solution was added, the precipitate was stirred vigorously with a glass stirring rod. Final solution occurred readily at room temperature within fifteen to thirty minutes. The globulin solution was transferred to a double thickness, Pyrex, conical centrifuge tube and spun down in an angle centrifuge for fifteen minutes at 1,500 revolutions per minute. Only a slight amount of insoluble material remained and this was discarded. The clear solution was lyophilized in 1 cc amounts and stored at room temperature. This material is referred to as "globulin fraction No. 1" which represents a ten times concentration as compared with the native serum.

The "supernatant fraction" obtained from this first phase of dialysis was again subjected to eighteen hours of dialysis exactly as described for the first period. The precipitate which formed was collected in the same manner as stated for "globulin fraction No. 1." Inasmuch as it was slightly less in amount than the first precipitate, it was dissolved in only 5 cc of 0.9 per cent saline solution. The resulting solution was labelled "globulin fraction No. 2," constituting a twenty times concentration as compared with the native serum.

The "supernatant fraction" recovered following the second stage of dialysis was dialyzed a third time over a period of eighteen hours as already described in detail. The small amount of precipitate obtained was dissolved in 2 cc of physiologic saline solution. This was labelled "globulin fraction No. 3" and amounts to a fifty times concentration as compared with the native serum.

The final supernatant fluid recovered from the third dialysis was lyophilized in 10 cc amounts and is referred to as the "supernatant fraction." When employed for experimental purposes the dried "globulin fractions" were dissolved in distilled water and the salt free "supernatant fraction" in 0.9 per cent saline solution in order to maintain isotonicity in all fractions.

EXPERIMENTAL

The Rh antibody content of the four fractions derived from serum (Ree) was determined by means of quantitative titrations in an experiment which was carried out in two parts. In Part I, all dilutions were made in physiologic saline solution, while in Part II, undiluted, normal, adult, human serum was used as a diluent. The experiment itself was performed as follows.

Decreasing amounts of (A) native serum, (B) "globulin fraction No. 1," (C) "globulin fraction No. 2," (D) "globulin fraction No. 3," (E) "supernatant fraction," volume 0.05 cc each were mixed with 0.05 cc of a 2 per cent suspension of washed Rh (cDE/c) group O cells. The tubes were shaken well, kept for one hour at room temperature and centrifuged for two minutes at 1,500 revolutions per minute. The resulting agglutination is shown in Table I.

"Globulin fraction No 1" contains a potent complete (saline) Rh agglutinin. "Globulin fractions No 2 and No 3" as well as the "supernatant fraction" are devoid of any complete (saline) Rh antibodies. It should be kept in mind that the "globulin fractions" compared with the native serum are 10, 20, and 50 times concentrated respectively. When undiluted, human serum is used as a diluent, the native serum reveals the presence of Rh agglutinins, again exhibiting a definite zone phenomenon in the middle of the series of dilutions. "Globulin fractions No 2 and No 3" contain Rh antibodies of the incomplete (albumin) variety, decreasing in strength in a straight line upon dilution, indicating that it is possible to separate the complete and the incomplete Rh antibodies by dialysis. Obviously, therefore, prolonged dialysis of the serum has resulted finally in the precipitation of "globulin fractions" containing the incomplete (albumin) Rh antibodies also.

This experiment might well be compared with the Experiment I described in the first paper of this series.¹ The single eighteen-hour dialysis did not bring about the precipitation of the incomplete (albumin) Rh agglutinins which remained in solution. Nevertheless, even after three eighteen hour dialysis periods, a certain amount of incomplete (albumin) Rh antibodies still remains in the "supernatant fraction" which exhibits a strong prozone phenomenon.

The question arose whether the "supernatant fraction" remaining after dialysis of serum (Rec) for three days would still contain the blocking antibody described in the preceding communication.² In order to clarify this point the following experiment was carried out.

I Method of Sensitization of Rh Positive Cells —

- 1 0.5 cc of a 10 per cent suspension of three times washed Rh_c (cDE/c) Group O cells was added to four rows of six tubes each.
- 2 Increasing dilutions (1) undiluted, (2) 1/3, (3) 1/9, (4) 1/27, (5) 1/81, and (6) 1/243 of the following materials were added in a volume of 0.5 cc per tube as follows:

Row (A)	Native (untreated) serum (Rec)
Row (B)	"Supernatant fraction" of serum (Rec)
Row (C)	Normal adult serum
Row (D)	"Supernatant fraction" of a normal adult serum
- 3 After shaking the tubes they were kept for thirty minutes in the refrigerator at 4° C.
- 4 The tubes were centrifuged for ten minutes at 4,500 revolutions per minute and the supernatants were aspirated and discarded.
- 5 The sediments, consisting of packed red blood cells, were washed thoroughly three times, using 5 cc of ice cold 0.9 per cent saline solution per tube.
- 6 Following the third washing, all of the saline solution was removed by aspiration.
- 7 0.5 cc of undiluted, normal, adult, human serum was added to each tube and the cells were resuspended completely in the serum.

II Method of Testing the Sensitized Rh Positive Cells for Agglutination With Anti Rh Sera—The experiment was set up in triplicate. To 0.05 cc of the cell suspensions of each of the tubes of rows (A) to (D), pipetted into a new series of small tubes, was added in Part I, 0.05 cc of undiluted anti D (Rh₀) serum containing Rh agglutinins of the complete (saline) variety, in Part II, 0.05 cc of undiluted anti D (Rh₀) serum containing Rh agglutinins of the incomplete (albumin) variety, and in Part III, 0.05 cc of undiluted, normal, adult, human serum. After standing for forty five minutes at room temperature the tubes were centrifuged for two minutes at 1,500 revolutions per minute. The resulting agglutinations are seen in Table II.

All dilutions made with undiluted normal adult human serum of Group O

As can be seen from Experiment II, blocking antibodies are present in the "supernatant fraction" of serum (Ree). The inhibitory effect of the "supernatant fraction" manifests itself against both the complete (IB) and the incomplete (IIB) varieties of anti-D (Rh_0) antibodies, though stronger against the complete (saline) Rh agglutinins. The native serum (Ree), too, inhibits the complete (saline) anti-Rh agglutinins (IA). Strangely enough, however, it fails to inhibit the agglutination of Rh-positive cells by the incomplete (albumin) variety of anti-Rh agglutinins (IIA). The failure of Rh positive cells previously sensitized by the native serum (Ree) to be agglutinated when taken up in undiluted, normal, adult, human serum (IIIA)* confirms the observations made in the preceding paper² that the incomplete (albumin) variety of Rh antibody can be removed from sensitized cells, to a great extent at least, by multiple washings.

An attempt now was made to demonstrate in the native serum proper the presence of blocking antibodies against the incomplete (albumin) Rh antibody by subjecting Rh-positive cells sensitized by the native serum to a more thorough washing procedure than that used in the preceding experiment. To this end the following experiment was carried out.

I Method of Sensitization of Rh Positive Cells —

- 1 0.1 cc of a 10 per cent suspension of three times washed heterozygous Rh, (cDE/e) Group O cells was added to eight rows consisting of ten tubes each.
- 2 Increasing dilutions (1) undiluted, (2) 1/3, (3) 1/9, (4) 1/27, (5) 1/81, (6) 1/243, (7) 1/729, (8) 1/2,187, (9) 1/6,561 and (10) 1/19,683 of the following materials were added in a volume of 0.1 cc per tube as follows:

- Row (A) Native (untreated) serum (Ree)
- Row (B) "Supernatant fraction" of serum (Ree)
- Row (C) Normal, adult serum
- Row (D) "Supernatant fraction" of a normal, adult serum

The experiment was set up in duplicate.

- 3 The tubes were shaken and kept for thirty minutes at 4° C.
- 4 After centrifuging the tubes for ten minutes at 3,000 revolutions per minute the supernatants were aspirated and discarded.
- 5 The sediments, consisting of packed red blood cells, were washed thoroughly four times using 2 cc of ice cold 0.9 per cent saline solution per tube.
- 6 After the fourth washing all of the saline solution was removed completely by aspiration.
- 7 0.1 cc of undiluted, normal, adult, human serum was added to each tube and the cells were resuspended in the serum.

II Method of Testing the Sensitized Rh Positive Cells for Agglutination with Anti Rh Sera — In Part I, 0.1 cc of 1/3 diluted anti D (Rh_0) serum containing Rh agglutinins of the incomplete (albumin) variety was added to each of the tubes, and in Part II, 0.1 cc of undiluted, normal, adult, human serum was added to each of the tubes. The tubes were allowed to stand at room temperature for one hour and were centrifuged for two minutes at 3,000 revolutions per minute. The agglutination as read macroscopically is recorded in Table III.

*Weak agglutination obtained in the first two tubes in Row (A) of Part I can be explained by the presence of traces of Rh antibodies not yet completely removed by washing as indicated by an identical reaction in the first two tubes of Row (A) of Part III in which undiluted normal adult, human serum was used as a control in place of anti Rh serum.

All dilutions made with undiluted normal adult human serum of Group O

Experiment III shows that blocking antibodies against the incomplete (albumin) Rh antibody can be demonstrated even in the native serum (Ree). Their demonstration is made possible only by thoroughly washing the sensitized Rh positive cells a procedure which apparently is necessary to remove Rh antibodies other than the blocking variety which remains attached to the cells in spite of the washing.

Coombs Mourant, and Race⁶ have described an important technique which permits the detection of sensitization of Rh positive cells by Rh antibodies. Rh positive cells sensitized by Rh antibodies without showing visible agglutination are washed several times and then agglutinated by the addition of an antihuman serum rabbit serum. It was of interest to find out which position the Coombs test would assume in the detection of Rh antibodies as found in the various fractions of the Rh antiserum (Ree). The following experiment was carried out to elucidate this problem.

I. Method of Sensitization of Rh Positive Cells—

- 0.1 cc of a 10 per cent suspension of washed heterozygous Rh (CDe/ce) cells belonging to blood Group O was added to each of twelve tubes in six rows.
- Increasing dilutions (1) undiluted (2) 1 3 (3) 1 9 (4) 1 27 (5) 1 81, (6) 1 243 (7) 1 729, (8) 1 2187, (9) 1 6561 (10) 1 19683, (11) 1 59049, and (12) 1 177147 of the following materials were added in a volume of 0.1 cc per tube as follows:

- Row (A) Native (untreated) serum (Ree)
- Row (B) ' Globulin fraction No 3 ' of serum (Ree)
- Row (C) ' Supernatant fraction of serum (Ree)

These titrations were performed in duplicate.

- The tubes were shaken and kept for thirty minutes in the refrigerator at 4°C.
- Following centrifugation for fifteen minutes at 3000 revolutions per minute the supernatants were aspirated from the tubes and discarded.
- The packed red blood cells in each tube were washed three times using 2 cc of ice cold 0.9 per cent saline solution per tube.

- 6 After the third washing all of the saline solution was removed as completely as possible by aspiration
- 7 In Part I, 0.1 cc of 0.9 per cent saline solution was added to each of the tubes, while in Part II, 0.1 cc of undiluted, normal, adult, human serum was added to each of the tubes and the cells were resuspended in the respective diluents

II Method of Testing the Sensitized Rh Positive Cells for Agglutination With Antihuman Serum Rabbit Serum—In Part I, 0.1 cc of 1:30 diluted antihuman serum rabbit serum was added to each of the tubes, and in Part II, an additional 0.1 cc of the same undiluted, normal, adult, human serum used for resuspending the cells was added to each of the tubes (control). The tubes were allowed to stand at room temperature for one hour and then were centrifuged for two minutes at 1,500 revolutions per minute. The resulting agglutination are seen in Table IV.

TABLE IV. COOMBS TEST

AGGLUTINATION BY ANTIHUMAN SERUM RABBIT SERUM OF RH POSITIVE CELLS SENSITIZED WITH NATIVE SERUM (REE) AND TWO OF ITS FRACTIONS RESPECTIVELY

11 1:59,049	++	++	-	-	-	-
12 1:177,147	+	++	-	-	-	-

The exceeding sensitivity of the Coombs test is evident from this experiment. It allows the detection of the sensitization of Rh-positive cells by the native serum (Ree) up to the final dilution used (up to 1:177,000). The "supernatant fraction" of the serum (Ree) containing blocking Rh antibodies gives a positive Coombs test up to a dilution of 1:729, roughly corresponding to its content of blocking Rh antibody (see Experiment III). The strength of the Coombs test obtained with "globulin fraction No 3" is surprising. This "globulin fraction" contained Rh antibodies of the incomplete (albumin) variety demonstrable up to dilutions not higher than 1:256 (see Experiment I) and yet the Coombs test is still definitely positive with the highest dilution used in this experiment (1:177,000). This finding is even more surprising if one considers the results of Part II of this experiment. Rh-positive test cells treated in an exactly identical way as in Part I were resuspended in undiluted adult serum without showing any trace of agglutination, pointing to the fact that the incomplete (albumin) Rh antibodies originally present were washed away or at least rendered ineffective by the washing procedure. It should also be mentioned that in experiments not reported in this paper, "globulin fraction No 3" was found to be devoid completely of Rh blocking antibodies.

DISCUSSION

Dialysis has been used during the last three years in this laboratory as a means of splitting anti Rh sera into two fractions namely the precipitate referred to as the globulin fraction and the supernatant fraction which was obtained following removal of the precipitate by centrifugation. As previously reported³ the precipitate frequently contained the complete (saline) Rh antibody while the incomplete (albumin) Rh antibody was found in the supernatant. In this manner certain anti Rh sera which were useless as test sera could be made into potent reagents for Rh determinations using the globulin fraction. This fraction can be concentrated easily depending upon the volume of saline solution in which it is dissolved. The method also proved that Rh antibodies of different varieties might be separated from each other because they apparently are associated with different protein fractions of serum.

In this paper a more quantitative method was used. Dialysis was continued over a period of three days during which time precipitates formed after each eighteen hour period were collected separately and examined for their Rh antibody content. Prolonged dialysis finally led to the precipitation of a good portion of the incomplete (albumin) variety of Rh antibody. However the remaining supernatant fluid still contained an Rh antibody with typical blocking qualities. It seems doubtful whether further dialysis would have resulted also in precipitation of this type of Rh antibody. It should be interesting to find out how the method of fractionated alcohol precipitation, as carried out by Cohn and associates compares with the relatively simple procedure of dialysis used in the investigations reported. It seems unlikely that dialysis in the cold denatures proteins at all which might give this method a certain advantage over others.

Differences in avidity among the various types of Rh antibodies manifest themselves upon washing sensitized Rh positive cells. The incomplete (albumin) variety of Rh antibody can be rather easily washed off with three or four thorough washings as proved by the fact that Rh positive cells previously sensitized with this type of Rh antibody and then washed failed to be agglutinated when suspended in undiluted adult human serum or albumin solution respectively. It was not possible, however, to remove the blocking type of Rh antibody present in the 'supernatant fraction' of serum (Ree) even by a series of thorough washings. As a matter of fact, the blocking effect of the native serum (Ree) became apparent only following washing procedures. As one might speculate the blocking type of Rh antibody tiles over and readily combines with the Rh antigens which become available following the removal of the incomplete (albumin) Rh antibodies.

The name blocking antibody used in this paper denotes an Rh antibody which not only fails to agglutinate but even interferes with the agglutination of Rh positive cells when they are suspended in an albumin containing medium. It should be recalled that Wiener previously called the incomplete (albumin) variety of Rh antibody the 'blocking' antibody because it prevented agglutination of Rh positive cells by the complete (saline) variety of Rh antibody in

physiologic saline solution. However, this blocking effect of the incomplete (albumin) Rh antibody was evident only when physiologic saline solution was used as a diluent, but not in undiluted serum or in albumin solution. The blocking antibody described in this paper inhibits agglutination of Rh positive cells even in an albumin-containing medium and it truly blocks the incomplete (albumin) variety of Rh antibody as well as the complete (saline) variety.

Therefore, the existence of three varieties of Rh antibodies can be assumed: (1) the complete or saline variety, (2) the incomplete or albumin variety, and (3) the blocking variety of Rh antibody. On the basis of their studies, Hill and Habelman^{8,9} already felt that there were three types of Rh antibodies, namely (1) the classical agglutinin, (2) the "blocking" antibody (as determined by Wiener), and (3) the "erythroagglutinoid" (as determined by the developing test^{8,9} or Coombs test¹⁰). The experiments reported in this paper, moreover, point to the likelihood that there is a fourth type of Rh antibody for the following reasons. Experiment IV of this paper reveals the rich content of Coombs antibody in 'globulin fraction No 3'. This 'globulin fraction No 3' also contained an incomplete (albumin) Rh antibody with a titer of 256. However, following multiple washings of Rh-positive cells sensitized with this 'globulin fraction,' no agglutination was demonstrable when the washed, sensitized cells were suspended in undiluted, normal, adult serum. Apparently washing had removed the incomplete (albumin) Rh antibody. Nevertheless, the Coombs test carried out with washed Rh-positive cells sensitized with the 'globulin fraction No 3' showed the presence of an Rh antibody with a titer of at least 177,000. This observation strongly suggests, therefore, that we are dealing with a type of Rh antibody which neither agglutinates Rh positive cells nor exhibits a blocking effect. Still the possibility cannot be overlooked entirely that traces of incomplete (albumin) Rh antibodies, by themselves insufficient in strength to agglutinate the cells but sufficient to give a positive Coombs test, were still present and attached to the Rh-positive cells under investigation. However, the latter explanation is unlikely considering the difference in titer between the incomplete (albumin) Rh antibody on the one hand and the Coombs antibody on the other.

There seems to be a reciprocal relationship between the capacity of the various types of Rh antibody to agglutinate Rh-positive cells and their ability to be removed by washing, that is to say, Rh antibodies which produce visible agglutination of Rh-positive cells can be removed more easily by washing procedures than Rh antibodies that sensitize Rh-positive cells without producing visible agglutination. Considerable differences in the speed and strength of the union between the various Rh antibodies and Rh antigen must exist.

The so called unitarian conception of antibody functions is adhered to by the majority of immunologists at the present time. The well known various manifestations of antigen-antibody reactions such as lysis, agglutination, precipitation, and so on, are explained by this concept on the basis of physico-chemical differences of the antigen rather than of the antibody, depending mainly upon the size of the antigen and the medium in which the antigen-antibody reaction occurs. Therefore, the same antibody that might produce

precipitation in one instance could cause agglutination or lysis of cells under different experimental conditions. The investigations reported in this series of communications are dealing with antibody functions of identical specificity directed against one antigen only, namely the D (or Rh₀) antigen present in the same physicochemical state in red blood cells. Yet, antibodies directed against this antigen have been found to be associated with separate protein fractions of the antiserum and can be distinguished from each other by their avidity for this Rh antigen and by their reaction with it under various experimental conditions. It seems difficult to see how the findings reported can conform to the present unitarian concept of antigen antibody reactions which appears to need some revision or amplification.

Two theories present themselves in connection with the differences in the antibody functions reported. The first theory would postulate the existence of three or four varieties of independent Rh antibodies which are sharply separated from each other both by the nature of their functions as well as by their association with different protein fractions of the serum. In contrast the second theory might refuse to accept the existence of sharply separated antibody functions and rather hold to the belief in a gradual change of one antibody function into another, assuming the existence of an Rh antibody spectrum of changing activity.

CONCLUSIONS

1 Prolonged dialysis of an anti Rh serum (Rec) against measured amounts of distilled water for three eighteen hour periods resulted in the precipitation of globulins which were collected individually at the end of each eighteen hour period. Three fractions obtained in this way were referred to as globulin fractions No 1, No 2 and No 3 respectively. The clear supernatant fluid remaining at the end of the third period of dialysis was called the "supernatant fraction".

2 Globulin fraction No 1 revealed the presence of a complete (saline) anti Rh agglutinin which was not found in any other fraction.

3 Globulin fractions No 2 and No 3 contained an Rh antibody of the incomplete (albumin) variety.

4 The supernatant fraction still containing Rh agglutinins of the incomplete (albumin) variety, exhibited a strong prozone phenomenon.

5 The prozone phenomenon of the supernatant fraction is attributed to the presence of a peculiar Rh antibody which inhibits agglutination of Rh positive cells by both the complete (saline) and the incomplete (albumin) variety of Rh antibodies. It acts therefore, as a true blocking antibody (third variety of Rh antibody).

6 The presence of this Rh blocking antibody also could be demonstrated in the untreated native anti Rh serum (Rec) by subjecting Rh positive cells sensitized with this serum to thorough washing procedures which apparently resulted in the removal of the incomplete (albumin) variety of Rh antibody.

7 Rh positive cells sensitized with globulin fraction No 3 failed to show macroscopically visible agglutination after being washed thoroughly and

suspended in undiluted, normal, adult, human serum. This fraction contained only incomplete (albumin) Rh antibodies of low titer and was devoid of Rh blocking antibodies. Nevertheless, cells sensitized with it were strongly agglutinated following the addition of antihuman serum rabbit serum (Coombs test), suggesting the existence of a fourth variety of Rh antibody.

8. The occurrence in one anti-Rh serum of certainly three and possibly four varieties of Rh antibodies of the same specificity, anti-D (Rh_o), but of different functions is described. They produce at the extremes of the spectrum of their activity either agglutination or blocking of Rh-positive cells with one variety standing in between which causes neither phenomenon, being demonstrable only by means of the Coombs test. The possible significance of these findings in relation to the validity of the present unitarian concept of antibody functions is discussed.

METABOLISM TOXICITY AND MANNER OF ACTION OF GOLD COMPOUNDS IN THE TREATMENT OF ARTHRITIS

VIII THE EFFECT OF BAL AND OTHER THIOL COMPOUNDS IN PREVENTING THE INHIBITION OF OXYGEN CONSUMPTION OF RAT TISSUES PRODUCED BY GOLD SALTS

WALTER D. BLOCK, PH.D., NAOMI C. GLIB, M.S., AND
WILLIAM D. ROBINSON, M.D.
ANN ARBOR, MICH.

BOTH organic and inorganic gold compounds have been used for many years in the treatment of rheumatoid arthritis. The value of this form of treatment is subject to argument and final appraisal on the basis of therapeutic trial apparently is difficult or impossible. The use of gold compounds in rheumatoid arthritis remains on an empirical basis, and even with carefully controlled administration toxic reactions have been a limiting factor in their use. In order to place this form of treatment on a more rational basis information regarding the manner by which gold salts produce their effects in the body must be available.

An intensive study of the metabolism and toxicity of the various gold compounds used has been made in this laboratory.¹ It was found that when gold compounds are injected intramuscularly into white rats the gold is deposited in various tissues of the body, primarily in the liver and kidney.² The amount and site of deposition seem to depend on the physical properties of the compound studied. Also, the severity of the histopathology in gold-treated animals is roughly proportional to the quantity of gold laid down in the tissue.

We became interested in whether the respiration of these tissues as measured by oxygen consumption, is influenced by the presence of gold and whether a correlation exists between the concentration of gold in the tissue and its rate of respiration. If such a relationship between deposition of gold and activity of the enzyme systems in these tissues exists it may provide an insight into the mechanism of gold toxicity. Using the Warburg technique it was found that the oxygen consumption of rat kidney and liver slices was inhibited *in vitro* by the inorganic compounds gold chloride and gold sodium thiosulfate. The organic compounds sodium succinimido aurate, gold sodium thiomalate and gold thioglucose did not cause inhibition.³

When 2,3-dimercaptopropanol (BAL) developed during the war as an effective antidote against acute arsenical poisoning became available it was shown to be effective also against other heavy metals: cadmium, mercury, zinc and copper.⁴ Furthermore recent reports indicate the apparent clinical value of BAL in treating gold toxicity in human beings and suggest that its administration results in an augmented urinary excretion of gold under these conditions.^{5, 6}

Received for publication Aug. 6, 1948

It is now generally accepted that the toxicity of heavy metals, such as arsenic, is due to the inactivation of the sulfhydryl groups in enzyme proteins of the tissues. The action of the thiols is attributed to their effective competition for the heavy metal with the sulfhydryl groups in various body proteins. Arsenic and gold are closely related chemically and it is reasonable to assume that their biochemical reactions are similar. It is suggested that the toxicity of gold is due to its combination with sulfhydryl groups in enzyme proteins, and the sulfhydryl (thiol) groups in BAL compete effectively for the gold combined in the tissue protein, thus restoring the normal enzyme system.

This study is concerned with the effect of BAL and other thiol compounds on the respiration of tissues *in vitro*, and their possible effect in preventing inhibition of oxygen consumption produced by gold compounds. Obviously, only those gold compounds observed to produce such inhibition in previous studies could be investigated.

METHODS

Measurements of oxygen consumption were made with the usual type of Warburg constant volume manometer. The carbon dioxide produced was absorbed by 0.3 cc of 20 per cent potassium hydroxide solution contained in the central well on pleated filter paper. After introduction of the tissue slice, the manometer flasks were immersed in a water bath at 38° C, flushed with pure warm oxygen (38° C) for ten minutes, and shaken at a rate of 110 oscillations per minute. The suspending medium was a phosphate buffered physiologic salt solution (pH 7.4) containing 0.2 per cent glucose as described by Krebs.¹⁸ The total volume of fluid in each flask was 2.5 cubic centimeters.

The tissues were taken from healthy male and female white rats which had been fed a standard stock diet. The animals were killed by a blow on the head and the kidneys and/or liver were quickly removed, washed free of blood, and placed in the buffer solution. Slices of approximately equal size and thickness were made with a razor blade held against the lower side of a glass microscope slide. The sections then were placed in the main chamber of the manometer flasks. At the conclusion of the experiment the slices were removed and dried for twenty-four to forty-eight hours at 75° C and oxygen consumption was calculated per milligram of dry weight of tissue.

The solutions to be tested were placed in the side arms at 12.5 times the final concentration and tipped into the main chamber containing the tissues after a control period of forty-five minutes. In all cases the final gold concentration was $M/500$ with respect to gold, since this had been shown to be the lowest concentration which would produce maximal inhibition of oxygen consumption.⁶ The thiol compounds were added in concentrations to provide either one thiol or three thiol groups for one atom of gold. This was done since it is possible for gold to react either as a univalent or trivalent ion. The pH of each added solution was adjusted so that the final pH of the solution in the flasks after addition was 7.4.

Each set of experiments included a control tissue slice, one to which gold was added, one with an added thiol compound, and one with both a gold and a thiol compound added. Readings of the manometers were made at fifteen and thirty-minute intervals, and were continued from one hour and forty-five minutes to two hours and forty-five minutes after addition of solutions being tested.

OBSERVATIONS

The compounds studied are listed in Table I. The inorganic gold salts, gold chloride and gold sodium thiosulfate, were previously shown to have a marked inhibitory effect on the oxygen consumption of rat tissues.⁶ Cystine and methionine were included since it was felt that they might be broken down to give compounds with a thiol group.

†Sodium thioglucose was furnished by the Schering Corporation Bloomfield N J

Only the results with kidney slices are included in this report. Essentially the same results were obtained with liver slices however since the oxygen consumption of normal liver tissue is smaller than that of kidney tissue the absolute differences noted with the compounds studied are much smaller than those found in the kidney.

Oxygen consumption of rat kidney slices as influenced *in vitro* by the gold compounds alone, by thiol and dithiol compounds alone and by a combination of each, is shown in Fig 1 for gold sodium thiosulfate and Fig 2 for gold

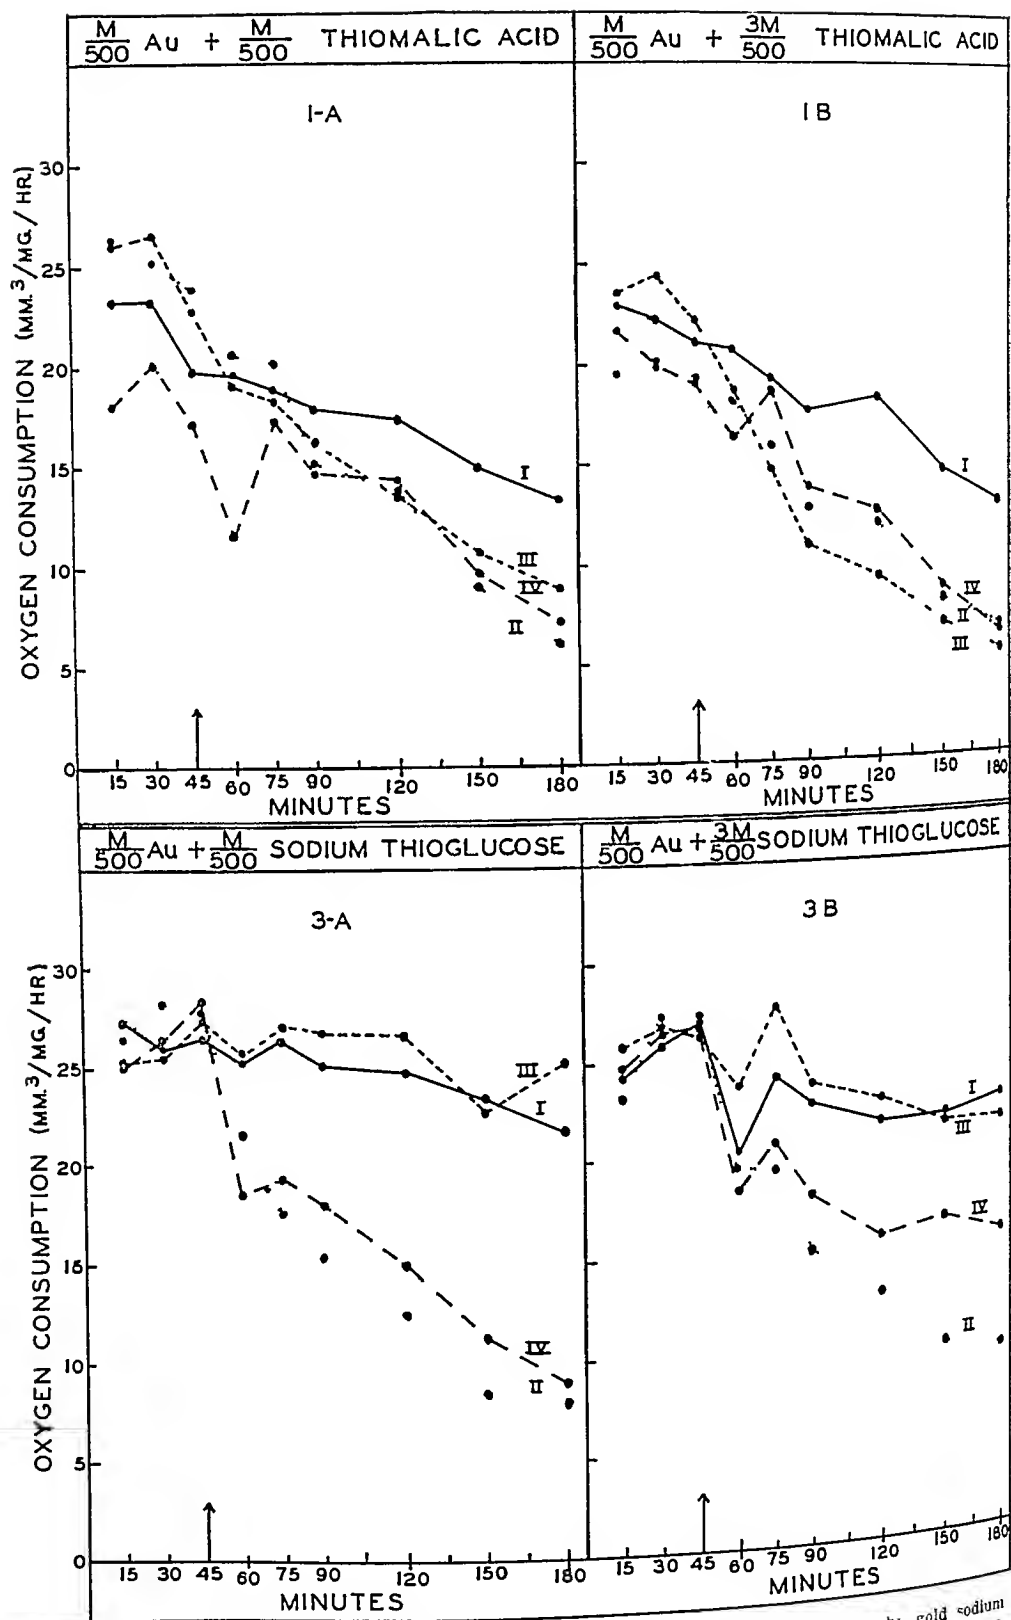

Fig 1—Oxygen consumption of rat kidney slices as influenced in vitro by gold sodium thiosulfate alone by thiol and di-thiol compounds alone and by a combination of each I — No compounds added II Gold sodium thiosulfate added III --- Thiol compound added IV - - Gold and thiol compounds added The vertical arrow indicates time of addition of compound tested

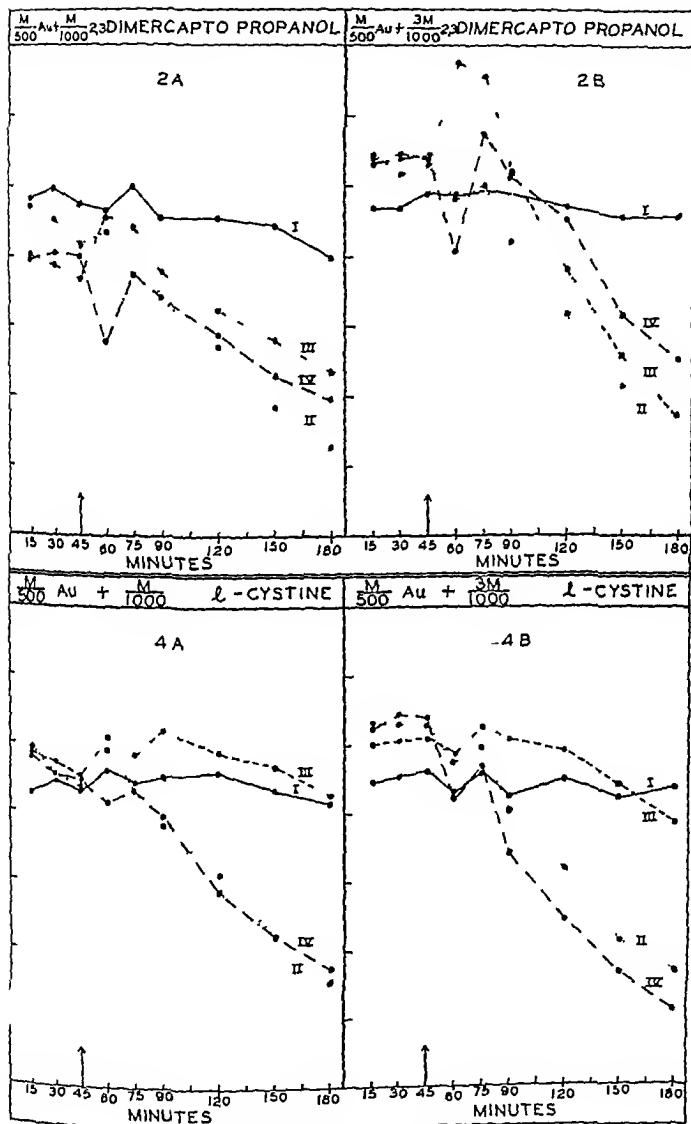

Fig 1—Continued. See legend on opposite page

chloride Oxygen consumption is plotted on the vertical axis against time in minutes on the horizontal axis. The arrow at forty-five minutes indicates the time of additions to the flask. Each curve represents the average of six to eight determinations. The control curve is shown by the solid line, the gold by a dotted line, thiol compound by a broken line, and both compounds by a combination dot-dash line. On the left, in each pair of experiments, the chart shows the results obtained when one thiol group was provided per atom of gold, on the right, the curves represent results with three thiol groups per atom of gold.

Gold Sodium Thiosulfate (Fig. 1)—The first pair of curves, 1-A and 1-B, shows the effect of thiomalic acid and gold sodium thiosulfate on oxygen consumption of rat kidney slices. The control curves (I) in both sets of experiments show a gradual decline in respiration over the three-hour period. In the M/500 concentration (1-A) thiomalic acid (III) produces an inhibition of respiration somewhat less than that produced by M/500 gold (II). The addition of both compounds simultaneously to normal tissue results in a respiration (IV) slightly higher than when gold alone is added (II) but lower than with thiomalic acid alone (III). In the 3M/500 concentration (1-B) thiomalic acid itself (III) produces an inhibition of respiration greater than that caused by gold alone (II). However, the simultaneous addition of both compounds results in a curve (IV) which follows very closely that of gold alone (II), indicating that in this instance the inhibition of respiration is not the additive effect of the inhibition produced by each compound alone.

The effect of BAL (2,3-dimercaptopropanol) is shown in 2-A and 2-B. In both sets of experiments the control curves (I) show little decrease in respiration over the whole period. In the M/1,000 concentration (2-A), where one thiol group is provided per atom of gold, the BAL alone (III) produces less inhibition of respiration than does gold alone (II). The curve for the addition of both compounds (IV) shows less inhibition than when gold alone is added (II), but greater inhibition than that caused by the thiol compound alone (III). In the 3M/1,000 (2-B) BAL itself (III) produces an inhibition comparable to that of gold alone (II), however, the rate at which respiration decreases is slower with BAL than with gold. Tissue respiration after the addition of both gold and BAL (IV) is inhibited as compared with the control (I), but continues at a somewhat higher level than with either compound alone. Here again, the inhibitory effect of both compounds is not the sum of the effect of each alone, and it is possible that there is a greater prevention of respiratory inhibition caused by gold which is masked by the individual inhibitory action of either compound.

The influence of sodium thioglucose and gold sodium thiosulfate is shown by the curves in 3-A and 3-B. In concentrations of M/500, equimolar with respect to gold, the thiol compound (III) has no effect when compared with control tissue respiration (I). Its addition together with gold results in a respiration curve (IV) which shows definite inhibition though it is less than that produced by the addition of the gold salt (II). In the 3M/500 concentration, sodium thioglucose produces no inhibition of oxygen consumption (III).

when compared with the control respiration rate (I). However, the addition of both thiol and gold compounds results in a respiration curve (IV) which is significantly higher than that obtained when only gold is added (II).

The last pair of curves, *f 1* and *f B*, Fig 1 presents results obtained with l-cystine, a potential di thiol compound. In both sets of experiments, cystine itself produces respiration curves (III) which are similar to the control curves (I). In the M/1,000 concentration equimolar with respect to gold, cystine added simultaneously with gold (IV) produces an inhibition of respiration comparable with that caused by the gold salt alone (II). In the 3M/1 000 concentration, the addition of cystine with gold (IV) results in an even lower respiration rate than that produced by gold alone (II). Despite the fact that the pH of all solutions added was adjusted so that the pH of the reaction media was 7.4 after additions to the main chamber, we found that the gold solution plus the 3M/1,000 cystine resulted in a pH of over 8.0 at the conclusion of the experiment. This fact may account in these experiments for the observed respiratory inhibition which is greater than that caused by the gold salt alone.

Methionine, not shown in the figure gave essentially the same results as l-cystine.

Gold Chloride (Fig 2)—The *in vitro* effect of gold chloride and the various thiol compounds studied on the respiration of rat kidney slices is shown in Fig 2. The first set of experiments *1 A* and *1 B* shows the influence of thiomalic acid. Alone in M/500 concentration, this thiol compound has a depressant effect on respiration as shown by curve III; however when it is added with the gold salt the respiration rate (IV) is somewhat higher than that produced by the gold alone (II) though lower than with thiomalic acid alone (III). In the 3M/500 concentration (*1 B*), thiomalic acid and the gold salt added simultaneously produce a respiration curve (IV) which shows definitely less inhibition of oxygen consumption than when either compound is added alone. There is however, definite inhibition when this respiration rate is compared with the control (I).

Essentially the same results were obtained with BAL and gold chloride *2 A* and *2 B*, Fig 2 as with thiomalic acid and gold chloride. In the 3M/1 000 concentration (*2 B*), BAL shows a greater inhibition of respiration alone (III) than in the M/1,000 concentration (III *2 A*) but its ability to prevent inhibition is much more marked (IV, *2 B*) at this concentration than at M/1 000 (III *2 A*).

Both sodium thioglucose and l-cystine behave similarly, *3 A* and *3 B*, and *4 A* and *4 B*, respectively. Neither compound produces inhibition of itself (III). Each, when added with the gold chloride in concentrations to provide one thiol group per atom of gold, shows some prevention of inhibition (IV, *3 A* and *4 A*). In the larger concentration, three thiol groups per atom of gold, each compound shows a greater prevention of inhibition (IV) than when only one thiol group is provided per gold atom.

Methionine and cysteine were also studied. Neither produced inhibition of oxygen consumption by itself nor was there any appreciable prevention of the inhibition produced by gold chloride.

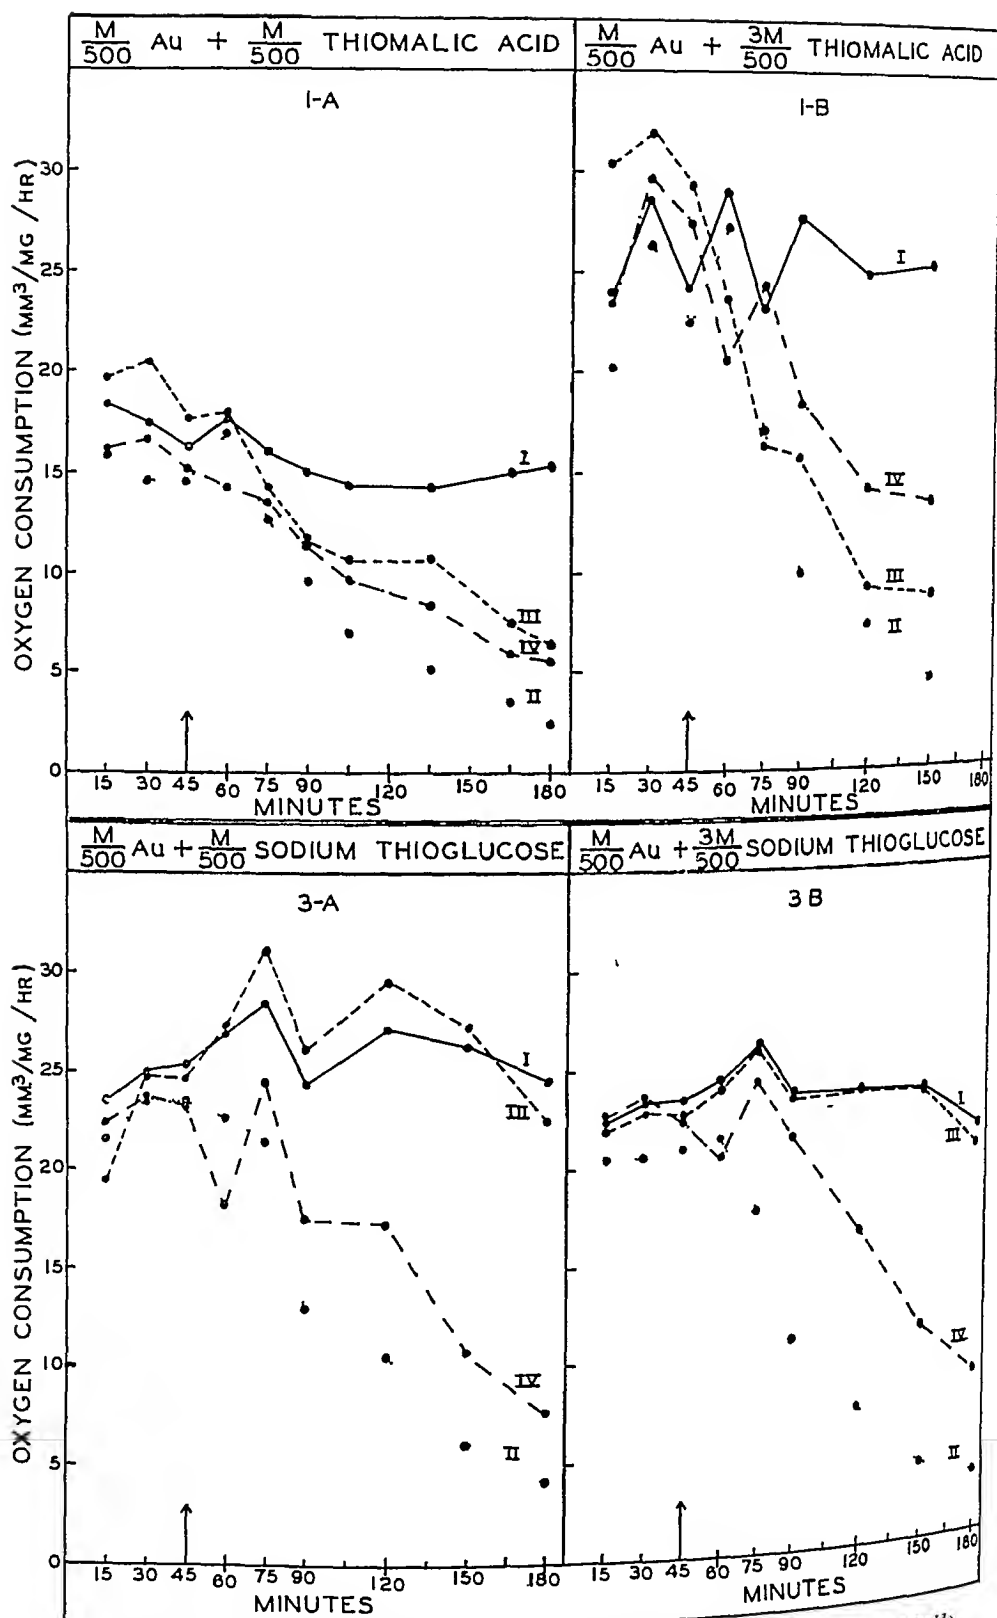

Fig 2—Oxygen consumption of rat kidney slices as influenced in vitro by gold chloride alone by thiol and di-thiol compounds alone and by a combination of each I — No compounds added II — Gold chloride added III — Thiol compounds added IV — Thiol and di-thiol compounds added The vertical arrow indicates time of addition of compound tested

DISCUSSION

With the exception of sodium thioglucose, none of the compounds containing a thiol or a potential thiol group definitely affected the inhibition in oxygen consumption caused by gold sodium thiosulfate. Yet all compounds except methionine and cysteine were effective against gold chloride. This could be most clearly demonstrated when three thiol groups were furnished for each atom of gold. However, both BAL and thiomalic acid produced an inhibition of oxygen consumption, when added alone, which was not evident with the other thiol compounds studied. The simultaneous addition of either of these with the gold sodium thiosulfate did not result in an additive effect with respect to respiratory inhibition. When either of these two was added with gold chloride, there was definitely less inhibition than was produced by either the thiol compound or the gold salt alone.

It appears that under conditions of these experiments, there is a chemical reaction *in vitro* between gold chloride and thiol groups to produce a compound which does not inhibit tissue respiration. The gold compounds theoretically formed, for example, gold thiomalate and gold thioglucose, were shown not to inhibit oxygen consumption in previous studies.⁶ Postulated compounds formed by the reaction of gold chloride and BAL or L-cysteine would be expected to behave similarly. We have no explanation for the failure of cysteine and methionine to counteract inhibition.

The results with gold sodium thiosulfate are not as clear cut. Because of the complicated chemical nature of this salt, it is difficult to postulate what compounds might be formed by the thiol derivatives.

The ability of thiol groups to remove gold deposited in tissues has not been investigated by this study. The work here presented has shown the ability of thiol compounds to lessen the *in vitro* inhibition of oxygen consumption when the compounds are used simultaneously with certain gold salts.

The implications of these studies with respect to the therapeutic uses of gold are not clear. Gold chloride is extremely toxic and has not been used in treating human beings. Yet it is the only salt which, under the conditions of this study, appears to be detoxified by various thiol groups. The inhibitory action of gold sodium thiosulfate is prevented only by sodium thioglucose, and not by the other thiol groups studied, some detoxifying action by BAL and sodium thiomalate may be masked by the fact that these compounds *per se* inhibit oxygen consumption.

The gold salts commonly used in the treatment of rheumatoid arthritis, gold sodium thiomalate and gold thioglucose, do not interfere *in vitro* with tissue respiration. Since in these two preparations the gold is bound to the organic moiety by a sulfur linkage, it is possible that the empiric development of therapeutic gold preparations has already taken advantage of the thiol detoxifying mechanism. This interpretation cannot be proved by *in vitro* studies, since it is possible that gold salts are metabolized by a common pathway, regardless of the form in which they are introduced into the body. Also, the failure of sodium succinimido-aurate, which contains no sulfur, to interfere with tissue respiration⁶ suggests that factors other than sulfur linkage may be important in determining toxicity.

SUMMARY

1 The *in vitro* inhibition of oxygen consumption of rat kidney slices observed with gold sodium thiosulfate is not lessened by the potential thiol compounds cystine and methionine, nor by BAL or thiomalic acid which contain thiol groups, however, sodium thioglucose does lessen the inhibition of oxygen consumption. The effects of BAL and thiomalic acid may be masked by the fact that these compounds, in themselves produce inhibition of respiration.

2 The *in vitro* inhibition of oxygen consumption of rat kidney slices caused by gold chloride is appreciably reduced by thiomalic acid, BAL, L-cystine and sodium thioglucose, but not by methionine or D-cysteine.

3 When three thiol groups are furnished for each atom of gold the reduction of inhibition is more clearly shown than when only one thiol group per atom of gold is present.

The oral hippuric acid liver function test was carried out in the manner described by Quick and commonly used in clinical medicine. As in the foregoing procedures, when para-aminobenzoic acid was used, its administration was started eighteen hours before the ingestion of sodium benzoate and it was given every three hours. When glycine was used, 20 Gm were given with breakfast and 20 Gm with the sodium benzoate.

RESULTS

When three subjects of similar height and weight were given orally a single 3 Gm dose of sodium salicylate, the plasma salicylate level reached its peak of 18 to 22 mg per 100 cc in two to four hours and then fell rapidly to 1 mg or less per 100 cc in twenty-eight to thirty-two hours. However, when the procedure was repeated and para-aminobenzoic acid was also given, the plasma salicylate level again reached its peak in two to four hours but fell more slowly. In one subject the plasma salicylate level dropped to 1 mg per 100 cc in forty-eight hours, and in the other two subjects it was more than 3 mg per 100 cc at fifty-six hours. Fig 1 shows results obtained on Subject 4 plotted on arithmetic graph paper and Fig 2 shows the same results plotted on semilogarithmic paper. Oral administration of para-aminobenzoic acid appeared to cause the plasma salicylate levels to fall more slowly and to alter the form of the curve.

Table I shows the salicyl fractions found in the urine of Subject 4 in the foregoing study. In man, after oral administration of the single dose of salicylate, there were the expected large quantities of salicyluric acid present in the urine. However, when para-aminobenzoic acid was given with the salicylate only very small quantities of salicyluric acid were found in the urine in spite of collection of the urine for a period almost twice as long. The quantities of free salicylate and salicyl glucuronate were comparable when the duration of the collection period was considered. There was no retention of salicyluric acid in the blood when it failed to appear in the urine, as the plasma salicylate was practically all in the form of free salicylate and only the usual traces of salicyluric acid were present.

TABLE I THE SALICYL FRACTIONS RECOVERED FROM THE URINE OF SUBJECT 4 AND DOG 261 IN THE SAME STUDIES ILLUSTRATED BY FIGS 1 THROUGH 6

	60	With PAB	71.50	819.39	610.61	1,501.50
Dog 261	48	Without PAB	4.54	185.46	203.95	393.95
	48	With PAB	0	198.0	264.0	462.0

Four similar studies were done on two dogs, the salicylate was given orally twice and intravenously twice. The results on one dog are shown in Figs 3, 4, 5, and 6. Salicylate excretion was much slower in the dog than in man and when para-aminobenzoic acid was given, the rate of excretion of salicylate was not altered appreciably.

In the dog the administration of para-aminobenzoic acid did not change the salicyl fractions appearing in the urine. Only traces of salicyluric acid were

Fig 1—Salicylate concentration in the plasma of Subject 1 after administration of a single dose of 3 Gm of sodium salicylate. Three gram of para aminobenzoic acid were given every three hours throughout the experiment.

Fig —The same values as in Fig 1 plotted on semilogarithmic paper

present in the urine when salicylate alone was given. Table I shows the salicyl fractions found in the urine of Dog 261 in the foregoing studies.

Table II shows the renal clearance figures obtained on four human subjects. The clearance values of salicylate without para aminobenzoic acid ranged from 50.46 to 99.36 c.c. of plasma cleared per minute, with an average of 70.29 cubic

centimeters. The clearance values of salicylate when para aminobenzoic acid was given ranged from 22.76 to 32.41 cc of plasma cleared per minute, with an average of 27.53 cubic centimeters. The renal clearance of salicylate apparent

Fig 3—Salicylate concentration in the plasma of Dog 261 after the oral administration of 1 Gm. of sodium salicylate. One-half gram of para aminobenzoic acid was given every three hours throughout the study.

Fig 4—The values in Fig 3 plotted on semilogarithmic paper.

was reduced approximately 60 per cent when para-aminobenzoic acid was given. However, in calculating these clearance values the urine was hydrolyzed and the figure for the total salicylate present was used regardless of what salicyl

fractions were present. Since this clearance value is actually the resultant of all the clearance figures of the individual salicyl fractions appearing in the urine, not much information can be obtained from it.

salicyluric acid appeared in the urine. Since salicyluric acid has a higher renal clearance value than free salicylate and normally constitutes approximately 50 per cent of the total salicyl fractions excreted in the urine, the deficiency of this salicyl fraction caused a marked drop in the renal clearance of the total salicyluric acid. At the same time clearance of the free salicylate fraction remained essentially unchanged unless the pH of the urine was also decreased. However, when enough sodium bicarbonate was given with the salicylate and para aminobenzoic acid to produce a strongly alkaline urine, the clearance of the free salicylate fraction increased enough to mask completely the effect of the deficiency of

saheyluric acid on the total salicylate clearance. In an attempt to see if the quantity of available glycine was the limiting factor, glycine was given with the para aminobenzoic acid and saheylate but still only small quantities of saheyluric acid were found in the urine. The urine was consistently alkaline when glycine was ingested and the excretion of total saheylate was high because of the increased renal clearance of the free saheylate fraction.

In order to see if para aminobenzoic acid was capable of interfering with the conjugation of glycine with benzoic acid or its derivatives other than saheyluric acid the hippuric acid liver function test was used. Table IV shows that there was a great decrease of the formation of hippuric acid when para aminobenzoic acid was given and the exogenous glycine did not eliminate this effect.

COMMENT

The results of this study substantiate the finding of Dry, Butt, and Scheffler that the oral administration of para aminobenzoic acid caused an elevation of the plasma saheylate level in man. This elevation did not occur in the dog. The mechanism responsible for this elevation of plasma saheylate level in man appeared to be an alteration of the detoxication of saheylate.

According to the reports of Bertagnini,⁷ Tollens,⁸ Quick,⁹ Salt,¹⁰ Kapp and Coburn,¹¹ and Smith and co workers,⁴ man normally conjugates saheyluric acid with both glycine and glucuronic acid and the corresponding products saheyluric acid and saheyl glucuronates appear in the urine. Kapp and Coburn reported that approximately 80 per cent of the ingested saheylate was excreted in the urine as compounds containing the saheyl radicle and roughly 50 per cent of this was saheyluric acid. This conjugation probably occurs in the liver. Quick^{12, 13} has pointed out that the liver of the dog does not conjugate glycine with benzoic acid and its derivatives to the same extent as the liver of man and many animals, but does use glucuronic acid extensively in the conjugation of benzoic acid and orthohydroxybenzoic acid.

Working with rabbits Ellinger and Hensel^{14, 15} in 1914 first reported the excretion of acetyl para aminobenzoic acid after the feeding of para aminobenzoic acid. After this report, para aminobenzoic acid was widely used in the study of some of the mechanisms of detoxication in man as well as animals, and

the literature on the metabolism of the drug is extensive^{10,21} These reports indicate that, in man, para-aminobenzoic acid is conjugated with glycine and glucuronic acid and that the corresponding products appear in the urine in addition to acetyl-para-aminobenzoic acid

The findings in this study are in agreement with the foregoing observations in that only traces of salicylic acid were found in the urine of the dogs after the administration of salicylate, while in man large quantities of salicylic acid were excreted in the urine after the ingestion of salicylate When para-aminobenzoic acid was given to man with sodium salicylate, only traces or very small quantities of salicylic acid appeared in the urine Since there was no retention of salicylic acid in the blood when it failed to appear in the urine, its formation was apparently interrupted or markedly decreased Although the principal mechanism by which para-aminobenzoic acid increased the plasma salicylate level and decreased total salicylate excretion appeared to be the interruption of salicylic acid formation, para-aminobenzoic acid also tended to lower the pH of the urine and thus further decreased the total salicylate excretion by decreasing the renal clearance of the free salicylate fraction When the urine was made strongly alkaline by the administration of massive doses of sodium bicarbonate, the clearance of the free salicylate fraction increased, as observed by Smith and co-workers,⁴ and the effect of para-aminobenzoic acid was masked

Because of the fact that no relatively simple methods were available for determining the concentrations of the conjugated products of para-aminobenzoic acid in the urine or blood, no attempts were made to study the possible reciprocal effects of salicylic acid on the detoxication or excretion of para-aminobenzoic acid

SUMMARY

The oral administration of para-aminobenzoic acid appeared to have the following effects on the metabolism and excretion of salicylate in man First, it altered the detoxication of salicylate by interrupting or greatly depressing the conjugation of glycine with salicylate so that only very small quantities of salicylic acid appeared in the urine after ingestion of salicylate Second, it tended to lower the pH of the urine and thus decreased the renal clearance of the free salicylate fraction Third, it caused a decrease of the urinary excretion of total salicylate and a rise of the plasma salicylate level due to the foregoing effects

In dogs the administration of para-aminobenzoic acid did not alter the excretion of salicylate and did not increase the plasma salicylate levels

The administration of para-aminobenzoic acid appeared to decrease greatly the formation of hippuric acid as measured by the oral hippuric acid liver function test in man

These effects were temporary and completely reversible

USE OF PENICILLIN AND STREPTOMYCIN IN THE ISOLATION OF POLIOMYELITIS VIRUS FROM FECAL SPECIMENS

BEATRICE F. HOWELL, M.A.,* AND VOLHAMMIE H. BARNETT, B.S.*
MONTGOMERY, ALA

IN ORDER to help confirm the diagnosis of poliomyelitis that had been made in several epidemics during the past two years, it was necessary to recover the virus from fecal specimens. Melnick¹ has recommended methods of preparation by high-speed centrifugation, but because the instruments were not available, the etherization method of Paul and Trask² was used. Isolations of the virus were made in two epidemics but because so often the monkeys succumbed to peritonitis after several intra-abdominal inoculations, another method was sought to reduce the bacterial content without loss of virus activity.

It had been shown by various workers that the antibiotics penicillin and streptomycin have little effect on the virulence of certain viruses, while on the other hand they greatly reduce the associated bacteria. Parker and Diefendorf³ reported that the viruses of vaccinia, St. Louis encephalitis, and of equine encephalomyelitis were able to grow in the chicken embryo after addition of penicillin. Florman, Weiss, and Council⁴ had used streptomycin without any effect against influenza A virus, Hurst⁵ likewise found penicillin to be of use in the isolation of the latter virus, while Hodges⁶ obtained marked reduction of bacteria after the simultaneous inoculation of penicillin, streptomycin, and fecal specimen into eggs. Bradley and co-workers⁷ employed penicillin to inhibit bacterial growth in the isolation of Newcastle disease virus from contaminated chicken tissues, while Beaudette, Bruns, and Miller⁸ have recently advocated the use of a mixture of penicillin and streptomycin for the recovery of the latter virus from chickens. Because the organisms were inhibited and yet none of the viruses used were particularly affected by these antibiotics, the following studies were undertaken with the virus of poliomyelitis. Before testing the antibiotics directly on fecal specimens, it seemed advisable to determine both what effect penicillin and streptomycin might have on different dilutions of poliomyelitis virus and what might be the optimal concentrations for inhibiting bacterial growth.

Experiment 1 To Determine the Effect of Streptomycin and Penicillin on Different Dilutions of the MV Virus of Poliomyelitis—A 10 per cent aqueous suspension of monkey cord containing the MV† monkey passage virus of poliomyelitis was centrifugated at 6,000 revolutions per minute for thirty minutes in the angle centrifuge placed in the cold room. The supernatant fluid was diluted

* in Intranasal instillation total of 15 ml i abd intra abdominal inoculation total of 30 ml ic Intracerebral inoculation of 1 milliliter

1 100 and 1 500 and 15 ml of each dilution were frozen for future use. The antibiotics were then added to the remainder of the three dilutions (1 10 1 100 and 1 500) in such a concentration that each contained 1 250 units of penicillin and 25 mg of streptomycin per milliliter. After remaining one half hour at room temperature, Rhesus monkeys were inoculated intra abdominally with 16 ml of each treated dilution of virus and intranasally with 3 ml of each that remained untreated. Daily injections were made until a total of 32 ml of each material was given by the first route and 15 ml by the second. One milliliter of the 10 per cent suspension of MV virus was given intracerebrally to a fourth monkey as a control. All of the animals became completely paralyzed as shown in Table I Experiment 1. It was apparent that the antibiotics in these concentrations did not reduce the potency of MV virus diluted at least 1 500. In fact the results were more effective than when this same lot of MV virus was titrated in monkeys without either material. With intracerebral inoculations of 1 ml of each tenfold dilution from 10^{-1} through 10^{-5} , only the monkey receiving the first

dilution became completely paralyzed. However, when given larger amounts by the combined intranasal and intra-abdominal routes, both the animals receiving the 10^{-1} and the 10^{-3} dilutions showed typical paralysis.

Experiment 2 To Determine the Effect of Penicillin and Streptomycin on a Mixture of MV Polomyelitis Virus and Bacteria Found in Flies—To test the effect of the antibiotics on different virus concentrations in the presence of bacteria, tenfold dilutions of the MV strain were made in a suspension of flies that had been taken at the city dump. After centrifugation for thirty minutes at 6,000 revolutions per minute, each dilution was treated with the same concentrations of the antibiotics as used in Experiment 1. Likewise, Rhesus monkeys were inoculated with the same amounts of material given by the same routes as in Experiment 1. At the same time 1 ml. of the treated $1/10$ suspension was inoculated into a monkey intracerebrally, while another animal was given a similar dose of the untreated $1/10$ virus by the same route.

All but two of the monkeys became paralyzed as shown in Table I, Experiment 2. These two probably had an inapparent infection because both withstood a paralyzing dose inoculated intracerebrally at a later date. Likewise, it was of interest that the monkey (M-150) receiving an intracerebral injection of the treated fly material became typically paralyzed without developing a brain abscess.

Experiment 3 To Determine the Effect of Penicillin and Streptomycin on a Mixture of MV Virus and the Bacteria of a Normal Fecal Suspension—A 20 per cent suspension of normal feces was made in sterile distilled water. Tenfold dilutions of MV virus were prepared in this material and after a light centrifugation a portion of each dilution was frozen for future use. The remaining dilutions were run in the angle centrifuge for thirty minutes at 13,000 revolutions per minute. Sufficient of each dilution was prepared so that aliquot portions could be frozen and removed when needed. One half hour before the inoculations a 16 ml. vial of each dilution, 10^{-1} , 10^{-2} , and 10^{-3} , was thawed and the antibiotics quickly were added in an amount so that each dilution of virus contained 1,250 units of penicillin and 25 mg. of streptomycin. Rhesus monkeys were given five daily doses of 3 ml. of the untreated material intranasally and two daily doses of 16 ml. each of the treated dilutions intra-abdominally. One animal was injected with 1 ml. of the $1/10$ treated material intracerebrally.

As may be seen in Table I, Experiment 3, the virus diluted with fecal suspension was not as potent as that with the fly material. No paralysis occurred beyond the $1/10$ dilution. The same lot of frozen virus was used in both experiments. However, once again typical paralysis was produced by the intracerebral route without any evidence of bacterial contamination.

Experiment 4 Effects of the Antibiotics on Fecal Bacteria—The following experiments were made to determine the approximate optimal bacteriostatic concentration of the antibiotics which could be used with a 20 per cent fecal suspension.

(1) Penicillin (crystalline sodium G) and streptomycin (calcium chloride complex, Meick) were added to a 20 per cent normal fecal suspension in the concentrations shown in Table II. In one series the antibiotics had little effect upon

(2) Also, a comparison was made of the bacteriostatic effect of etherization with that of the antibiotics. A 20 per cent suspension of normal feces in sterile distilled water was centrifugated for ten minutes at 2,000 revolutions per minute to throw down the coarse particles. The supernatant fluid was removed and run in the angle centrifuge for thirty minutes at 13,000 revolutions per minute. Cultures were made on blood agar and in thioglycolate broth. The material was divided and one part was treated with 15 per cent ether and the other with varying concentrations of the two antibiotics. The etherized portion was shaken for thirty minutes in the cold room and left overnight, the ether was removed by suction the next morning. Cultures were made in the media mentioned.

As may be noted in Table III, the ether attenuated the development of aerobic bacteria on blood agar but did not reduce growth in the anaerobic liquid medium. On the other hand, organisms were inhibited on both types of media when practically all of the antibiotic concentrations were used.

From the results both of titrations in monkeys and of the cultural tests, it seemed evident that the use of penicillin and streptomycin would be advantageous in the isolation of the poliomyelitis virus from fecal specimens. The optimal concentrations for bacterially infected material appeared to be 1,000 units of penicillin and 20 mg of streptomycin per milliliter. These amounts retarded bacterial growth without reducing the virus potency. Therefore the method seemed sufficiently reliable for use on human fecal material.

Experiment 5 Use of the Antibiotics in the Preparation of Human Feces From Patients With Poliomyelitis—

With Known Positive Feces—Before trying this method on feces of unknown virus content, material was prepared from a human stool that had yielded poliomyelitis virus by the etherization method. This specimen had been kept frozen in the dry ice refrigerator for at least two months. A 20 per cent suspension in sterile distilled water was divided into two portions, one of which was treated with ether by the above-mentioned method and the other with the antibiotics essentially in the manner described under Experiment 3, except for the following differences. The dilutions were 1:5, 1:10, 1:50, and 1:100, and 1,000 units of penicillin and 20 mg of streptomycin were used per milliliter of dilution. Cynomolgus monkeys were inoculated throughout the experiment. The different dilutions of feces treated by the two methods were inoculated into the animals intraabdominally. The untreated suspensions were given intranasally.

TABLE IV COMPARISON OF VIRUS ISOLATION METHODS IN CYNOMOLGUS MONKEYS USING A SUSPENSION OF POSITIVE POLIOMYELITIS FECES

Penicillin and streptomycin	1 ml ic	Paralyzed	Paralyzed	0	0

Histopathologic sections on all paralyzed monkeys were positive for poliomyelitis.

* iabd Intra-abdominal in intranasal ic Intracerebral

A third series of monkeys was injected intracerebrally with 1 ml amounts of each dilution of feces treated with the antibiotics. As shown in Table IV, only the monkey given the 1:10 dilution of feces became paralyzed after the etherization method, while the animals given all three dilutions (1:5, 1:10 and 1:50) developed polomyelitis after employing the antibiotic technique. No animals developed peritonitis nor did any show evidence of a brain abscess when inoculated intracerebrally. It seemed apparent that better results were obtained in the isolation of the virus by the antibiotic method than by that of etherization. The former was also simpler and quicker to prepare.

With Feces From Patients with Suspected Polomyelitis—Fecal specimens obtained during the first week of illness were received from eight patients with suspected polomyelitis. Each sample was diluted in sufficient sterile distilled water to make a 20 per cent suspension which was then centrifugated for ten minutes at 2 000 revolutions per minute to throw down the larger particles. The supernatant fluid was removed. About 15 ml were saved and frozen in 3 ml amounts to be used for the daily intranasal instillations of *Cynomolgus* monkeys. The remainder of the material was put in the angle centrifuge for thirty minutes at 13 000 revolutions per minute in the cold room (9 to 10° C). The supernatant fluid was then kept frozen in 10 ml amounts until needed.

Thirty minutes before the inoculations were to be made 10 ml of the suspension were thawed rapidly and treated with 1 000 units of buffered crystalline sodium penicillin G and 20 mg of streptomycin (calcium chloride complex, Merck) per milliliter. After leaving the mixture for thirty minutes at room temperature cultures were made on blood agar and in thioglycolate broth. A monkey was then inoculated intra-abdominally with 10 ml of the treated material and intranasally with 3 ml of the untreated feces. The same amounts were repeated daily over a five day period until a total of 30 ml was given into the peritoneal cavity and 15 ml by the nasal route.

Four of the eight monkeys developed flaccid paralysis typical of polomyelitis within from six to eight days after the first injection. They were sacrificed and suspensions of the cord were passed intracerebrally to monkeys, guinea pigs, and albino mice. The passage monkeys likewise developed symptoms of polomyelitis but the other animals remained well. Histopathologic sections of the first passage monkey cord showed lesions of polomyelitis.

The results of these inoculations again indicated that the additions of penicillin and streptomycin in the quantities employed is a satisfactory aid in the isolation of the virus of polomyelitis from bacterially contaminated suspensions.

DISCUSSION

Although the treating of fecal specimens with ether in the isolation of the polomyelitis virus has yielded adequate results in determining the causative agent in an outbreak of suspected polomyelitis, there is always the risk of losing monkeys from peritonitis even if the bacterial counts seem negligible. If the peritoneal route is omitted and one depends solely on the intranasal instillations the quantity of material administered may not be sufficient unless the time period is increased. Therefore it is gratifying to find that one can satisfie

torily add penicillin and streptomycin in the afore-mentioned amounts to fecal or other bacterially contaminated material suspected of containing the virus of poliomyelitis

In attempted isolation of this virus from feces obtained in an earlier outbreak, five out of twenty-two monkeys (22 per cent) died from peritonitis after intra-abdominal inoculation of etherized specimens. After inaugurating the antibiotic method, no animals developed peritonitis out of the twenty five tested intra-abdominally, and none of the monkeys had a brain abscess after intra-cerebral injection of treated material. In applying this method, however, it is essential that the penicillin and streptomycin should be added to the fecal suspension after clarification in the angle centrifuge at 13,000 revolutions per minute. The virus is not sedimented at that speed and this type of machine may be available in most virus laboratories that do not have an ultracentrifuge. This method greatly reduces the time of preparation because the antibiotics react quickly and it is not necessary to leave the mixture in contact for more than thirty minutes.

As shown in the foregoing experiments (Tables I and IV), there is apparently no loss of virus potency because it may be recovered even after dilution of a fecal specimen 1:50, whereas the results were negative with this dilution when the same sample was treated with ether. There is sufficient evidence to show, therefore, that 1,000 units of penicillin and 20 mg. of streptomycin per milliliter do not materially inhibit the recovery of the poliomyelitis virus from contaminated material even though in a comparatively low concentration.

After this work was completed it was of interest to learn that Melnick⁹ had been adding these antibiotics to human feces processed in the ultracentrifuge and that Comita¹⁰ in Cuba also had been adding penicillin to fecal specimens with satisfactory results in the recovery of the poliomyelitis virus.

SUMMARY

It has been found that a mixture of 1,000 units of penicillin and 20 mg. of streptomycin per milliliter of material are the optimal concentrations to use for the inhibition of bacterial growth and the isolation of the virus of poliomyelitis from fecal specimens.

A method of isolating the virus from contaminated material has been described which has proved to be quicker and more efficient than the older etherization procedure.

Whereas previously five out of twenty-two (22.7 per cent) monkeys had developed peritonitis after intra-abdominal inoculation by the ether method, none of the twenty-five animals was lost after treatment of the suspensions with the antibiotics, and the same material could be used effectively by the intra-cerebral route as well.

The antibiotics did not prevent paralysis in monkeys when added to a 1:500 dilution of the MV strain, to a 1:1,000 dilution of MV virus and filtrate suspension, to a 1:10 dilution of MV virus and feces, or to a 1:50 dilution of a known positive fecal specimen.

With the new method, the virus of poliomyelitis was isolated from four out of eight (50 per cent) human feces taken during a recent outbreak of poliomyelitis.

THE EFFECT OF COMMERCIAL HEPARIN ON THE PLATELET COUNT

E FIDLAR, B A, M D, AND L B JAQUES, M A, PH D
SASKATOON, SASKATCHEWAN, CANADA

COPLEY and Robb¹ observed that when heparin was added to dog's blood *in vitro*, it failed to preserve the blood platelets. This was in contrast to the action of citrate which is presumed to preserve platelets because of its anticoagulant properties. The platelet count was lowered sharply within five minutes and after twenty-four hours showed reductions of from 30 to 100 per cent. Since the effect of heparin increased with its concentration and since Copley and Robb¹ also found that intravenous injections depressed the platelet count, there was indication of a direct action rather than a simple failure to preserve the platelets from unfavorable conditions *ex vivo*. This observation is of importance in considering the effect of heparin in the prevention of platelet thrombi. In the course of other studies on heparin, we have been able to confirm and extend the observations of Copley and Robb, and in a personal communication from Dr A J Quick we learn that our results on dogs agree in general with some recent findings at his laboratory.*

METHODS

Platelet counts were made from blood taken into Rees and Ecker's formalin citrate mixture recommended by Tocantins² and the technique of counting was in some cases modified by the use of 5 per cent urea solution as described by Fidler and Waters³ so that estimates of leucocytes could also be made in the same chamber in which the platelets were counted. Agglutination was estimated by counting clumps of three or more separately and expressing as a percentage of the total platelet count. In studying the influence of heparin on platelets outside the body, the silicone technique was used as described by Jaques, Fidler, Feldt and Macdonald⁴ in order to minimize the effect of foreign surfaces. Concentration of heparin is expressed in Connaught anticoagulant units. This is the activity of 1/100 mg of the crystalline barium salt or 1/110 mg of the sodium salt of beef heparin.

RESULTS

In a series of experiments designed to study the physiology of heparin, various doses of the anticoagulant were injected into dogs. The effect of these injections on red cell, white cell, and platelet counts is shown in Table I. Attention is directed to the following points:

(1) A fall in the platelet count occurred in all instances and in four reached a level of less than 10 per cent of the number before injection.

(2) Fifty units per kilogram had as marked an effect in one animal as 1,500 units per kilogram had in another, suggesting either individual variability or no

From the Department of Physiology, University of Toronto, Toronto, Canada and the Department of Physiology, University of Saskatchewan, Saskatoon.

Received for publication July 30 1948

*See p 1424

†All the heparin was supplied by the Connaught Medical Research Laboratories, Toronto, Ont., except one sample of Danish heparin obtained through the kindness of Dr Tage Astrup.

correlation between dosage and the extent of effect provided the dose was beyond some minimum and given in a single injection

(3) Agglutination of the platelets appeared in all samples taken two and one-half minutes to more than one hour after injection but clumping under ten per cent was not regarded as significant

(4) After single injections the count would recover from the initial fall but continuous injection would hold the count down although not at as low a level as followed the first injection

(5) On the whole, the leucocytes declined and returned parallel with the platelets after single injections but remained at a lower level with continuous injection

Continuous injection of 1 unit per kilogram per minute

In the first eight experiments platelet counts were made in the 1/10 dilution with urea.

In the last three experiments platelet counts were made in the 1/100 dilution

Fig. 1

The effects of continuous injection suggested that as long as heparin remained in the blood stream the counts would remain depressed. This was given further investigation in an experiment shown in Fig. 1 in which heparin concentration in the blood was determined by the method of Jaques, Monkhouse, and Stewart⁶. Four milligrams per kilogram of heparin were injected intravenously into a dog weighing 6.7 kilograms under pentobarbital anesthesia. Clotting times were determined by the method of Lee and White,⁷ using blood from the exposed femoral vein. After injection of the heparin the platelet count fell to one-third of the initial value and then rose again, moving inversely with the heparin in the blood. It will be noted, however, that when the platelets recovered to 80 per cent of the original count, there was still enough heparin present

TABLE II EFFECT OF INJECTED HEPARIN ON THE PLATELET COUNT IN L B J

Counts made in the 1/100 dilution

to prolong the clotting time to more than five hours. This extension of the anti-coagulant action beyond the effect upon platelets will be discussed later.

Table II shows the effect of heparin upon one of us (L B J) when administered both intravenously and subcutaneously. The latter route merely delayed and prolonged the thrombocytopenia.

Copley and Robb¹ showed that when mixtures of heparin and blood were stored *in vitro*, the greater part of the fall in the platelet count took place in the first forty or fifty minutes when compared with counts obtained at forty eight hours. In the hope of securing further information we made observations on blood handled by means of the silicone technique. Under proper conditions and without the addition of any anticoagulant it is sometimes possible by this method to obtain blood in which the platelet count remains practically unaltered for thirty minutes. Blood removed with a silicone syringe was transferred to small beakers coated with silicone and containing varying quantities of heparin. Since the controls with saline alone could not be used beyond thirty minutes controls in citrate were used in some instances. For storage the mixture was poured into a silicone test tube stoppered and placed in the refrigerator. In a few experiments a further control blood was also placed in a beaker without a silicone surface.

TABLE III BLOOD AND HEPARIN MIXED IN SILICONE VESSELS

PLATELET COUNTS IN FIRST SAMPLE AFTER MIXING				
SUBJECT	CONTROL MIXTURE		HEPARIN MIXTURE	
		PLATELETS/C MM × 1 000		UNIT/C C

	Saline	100	80	10
	Saline	185	120	10
	Saline	140	90	10

Table III gives a summary of samples taken as soon as possible after mixture in silicone vessels. The time of sampling would vary from a few seconds to about three minutes depending upon the manipulations required in different experiments. In only three of the fifteen examples did the count of the heparin mixture correspond with that of the control mixture within the error of the method, and in two of these it was lower than the value for the control. This demonstrates the promptness of the heparin's effect.

In Experiments A B C and G platelet counts were made in the 1/100 dilution.
In Experiments D E F and H platelet counts were made in the 1/10 dilution with urea.

Table IV gives the results obtained in later samples and attention is directed to the following points

(1) The decline initiated at mixing was continued to a low point depending on the time of sampling but varying from three minutes to twenty four hours

(2) In some instances a recovery occurred from this low point which could hardly be accounted for on the basis of irregular sampling

(3) Citrate controls observed for twenty four hours or more in three experiments showed a similar decline and recovery but less marked. Even a control in saline would sometimes show this within the half hour although the red and white cell counts were within the error of the method

(4) As in the experiments in vivo there appeared to be an individual variability

These findings raise several points of interest which will be discussed later

Platelet counts made in the 1/100 dilution

As a further test of the effect of heparin on platelets, a comparison was made of the counts *in vivo* with counts on the same blood *ex vivo*. Using the silicone technique, blood from a dog was added to heparin in a beaker and then heparin was injected into the same animal to bring the concentration in the circulating blood to approximately that in the beaker. An hour later another sample of blood was withdrawn and added to heparin in a silicone beaker. The results for two experiments are shown in Table V. Here it will be noted that

(1) The reduction that occurred immediately after mixing the first sample in the silicone vessel continued to a low point at seven minutes and reached a level approximating that found three minutes after injection into the animal.

(2) Blood drawn from the heparinized animal did not show the usual reduction in platelets immediately after mixing with fresh heparin in the beaker.

(3) In the second experiment three successive injections were each followed by a sharp decline in the platelets although at the time of the last two injections the blood was meoagulable.

(4) The counts in the second animal at the time of each injection were at successively lower levels and declined less with each successive injection.

Platelet counts were made by one of us (E. F.) in connection with experiments on heparin at Toronto in 1938-1941. On one occasion samples of blood which were taken into heparin instead of formalin-citrate gave unexpectedly low counts together with clumping. As a consequence, this technique was never repeated. On the other hand, there were experiments in which samples of blood which had been taken ten or fifteen minutes after injections of heparin showed no significant drop, although in the light of present experience some reduction would have been expected. These facts, together with some differences between our results and those of Wright,⁸ to be discussed later, raised the question of differences in samples of heparin and the possibility of an impurity in the commercial product we were using. No evidence of the latter possibility was found in fractional precipitation with brucine. There was no concentration of the agglutinating activity in any one fraction. After discussing the earlier experiences with Dr. A. M. Fisher* and Dr. A. F. Charles,* they very kindly provided certain experimental lots for comparison with the commercial product. Also through the kind cooperation of Dr. Tage Astriup a sample of Heparin Leo was obtained in powder form and was compared with a similar product from Dr. Charles. The results of this study are contained in Table VI.

Heparin I, the commercial sample, was already in solution in 10 c.c. vials with 0.3 per cent tricresol as preservative. Samples II to VI were experimental lots, but II differed from III only by the absence of tricresol. Samples VII and VIII were freshly dissolved in 0.9 per cent saline with 0.3 per cent tricresol and were used within an hour after solution. Sample VII assayed 110 units per milligram and sample VIII, the Heparin Leo, 100 units per milligram. All samples were given intravenously to dogs under Nembutal in a dose of 100 units per kilogram, and platelet counts were made before injection and at approximately four, ten, thirty, and sixty minutes afterwards. The figures are adjusted to the same basis relative to the erythrocytes. The following features are apparent in Table VI.

*Connaught Laboratories

- (1) One animal, C was distinctly more sensitive than the other three
- (2) With one exception the minimum agglutination coincided with the lowest count
- (3) With one exception the lowest count was obtained in the first sample after injection

Blood samples taken before injection and at four ten thirty and sixty minutes after except as follows: (a) at eleven and one half minutes (b) at three and one half minutes (c) at eleven minutes (d) at sixteen and one half minutes (e) at sixty two and one half minutes (f) at thirty and one half minutes.

Blood diluted 1/5 in formalin citrate. This 1:5 mixture diluted 1/10 with per cent urea solution for heparin dosage 100 units per kilogram.

(4) The sharpest reaction occurred with the commercial sample of heparin and was accompanied by a definite leucopenia

(5) Some experimental products given in the same dosage of anticoagulant units as the commercial one had much less effect upon platelets

DISCUSSION

These results agree with those of Copley and Robb² that the injection of commercial heparin into dogs will cause a transient thrombocytopenia. This result also has been found in man, as one of the authors (L. B. J.) demonstrated upon himself. Copley³ has found platelet emboli in the rabbit and hamster following injection of heparin. Hence the phenomenon appears to be a general one, although in mice Copley and Robb² did not demonstrate the platelet change as clearly as in dogs. In the latter they found the maximum thrombocytopenia to be about 40 per cent, whereas in seven of our dogs the decrease reached 90 per cent or more. This may be due to the fact that their samples were not taken until twenty-six or more minutes after injection, although in three of their animals studied at shorter intervals the lowest platelet count occurred in the first twenty minutes.

The lowest counts in our experiments appeared within three and one half to five minutes after intravenous injection. A slow rate of injection, 1,000 units per kilogram per minute, was practically as effective as a rapid rate, 1,000 units per kilogram per second. In the human subject, subcutaneous administration appeared to delay and prolong the effect of heparin but not to abolish it. Continuous injection at 1 unit per kilogram per minute held the platelet count down, though not at the low point reached by a single injection. During the period when the blood was uncoagulable from one injection of heparin, a second injection would again depress the count. In the first experiment, in Table V, the dose of 1,000 units per kilogram would prolong the clotting time to about eight hours, but the count in this animal returned to normal in one hour. Compared with the experiment shown in Fig. 1, the return of the count was more rapid in spite of the larger dose. This is another example of the individual variability encountered among dogs, but both instances favour the idea that some substance may render the heparin innocuous to platelets without inhibiting the anticoagulant power, or that the agglutinating action is a weaker property. It is interesting that the heparinized blood, drawn from the animal in Table V, when added to fresh heparin in the silicone beaker did not show the immediate drop in platelets commonly found with normal blood. This might mean greater resistance acquired by the platelet or perhaps the disappearance of sensitive platelets due to the injected heparin.

On the question whether the extent of the decline *in vivo* depends upon dosage, our data do not suggest any correlation. In Table I it will be seen that there was practically no difference in the extent of response to 50 units per kilogram in one animal and 1,500 units per kilogram in another, although in the latter instance there is evidence of a more prolonged effect if compared with the preceding experiment where 100 units per kilogram were used. In both Copley and Robb's² results and our own the differences point to individual variability.

In vitro however, where the same sample of blood can be used with varying doses Copley and Robb¹ showed that in strengths from 0.05 to 100 units per cubic centimeter the platelet count decreased as the heparin increased. Also they noted that this effect of heparin did not appear when it was added to citrated blood.

The mechanism of the swift disappearance and return of the platelets from the general circulation is not clear. The appearance of clumps of platelets in blood samples taken soon after the injection suggests that a filtering out of clumps in the capillaries is the cause of the sharp fall *in vivo*. But actual lysis may also be a possibility, and the increase in adhesiveness leading to agglutination may be merely an early stage of lysis. Wright⁸ in her study of adhesiveness, noted only about a 10 per cent decline in the count in eighty minutes when using heparin with blood in paraffined tubes. It is admitted that our method of estimating agglutination is only a rough approximation but if the data of Experiments D, E, and F Table IV, are examined it will be noted that the maximum agglutination occurred in the ten or thirty minute samples. Where the heparin used was 10 units per cubic centimeter or more considering samples only up to three hours, the maximum agglutination either coincided with the lowest count or appeared in the sample immediately preceding it. All samples of twenty four hours or later showed a decline in agglutination from the maximum. This corresponded with a rising tendency in the counts in two of the blood specimens (Experiments D and F), though in Experiment E the counts tended to remain low. This inclines us to the opinion that clumps can break up again, especially in the living animal where there may be some factor tending to neutralize the heparin effect as suggested in Table V. On the other hand we have observed in late samples large clumps in which it was impossible to count individual platelets and which gave the suggestion of coalescence as though undergoing a slow form of lysis.

Lysis is also suggested in the mixtures in silicone because samples taken simultaneously from the center, bottom and side of the beaker gave counts which were all within experimental error. For example in one experiment the count from the center of the beaker was 100,000 from saline 80,000 after three minutes in heparin, and 45,000 after thirty minutes in heparin. Other samples taken at the same time from side and bottom were within plus minus 5,000 per cubic millimeter. If the decrease in the count were due to settling of clumps or their adhesion to the walls of the vessel one would expect a greater variation.

Against the idea of lysis of the platelets as a major factor in the decline are first, the very rapid recovery and, second the absence of any symptoms which might be expected from materials known to be present in platelets (thromboplastin, vasoconstrictor substances, and so on).

The rapid return of the platelet count in some of the experiments *in vivo* was remarkable. In some cases after declining 60 to 75 per cent it reached the normal level again within an hour. This scarcely can be due to new formation of platelets. Lawienec and Valentine¹⁰ estimated production in the cat to be about 1,600 to 2,800 per cubic millimeter per hour. Tocantins¹¹ found 40,000 per cubic millimeter per hour following splenectomy but this rate could hardly

be expected from normal bone marrow. A count rising from 20,000 to 228,000 in thirty-two minutes (Table I) does not look like new formation. It may be noted also that since the count before heparin was 295,000 no great destruction by lysis is indicated.

The fact that the leucocytes tend to decline when the platelet count is very low suggests that they also are caught with the platelet clumps in the capillaries. In one experiment, freshly drawn blood was mixed with heparin in the syringe, placed in a plain glass test tube, and kept fifteen minutes at body temperature before reinjection. After the blood had been drawn back into the syringe, it was found that the wall of the tube had a deposit of fine granules which, when washed off in formalin-citrate, proved to be platelet clumps. Many of these were adherent to leucocytes.

It is unlikely that there is any direct destructive action of heparin on the leucocytes since counts of the latter were made on all samples in Experiments D, E, and F (Table IV) and failed to show the parallelism with the platelet counts usually found in vivo.

The silicone experiments require further consideration. They were planned as controls of the in vivo experiments on the assumption that since contact with glass could be avoided, the conditions outside the body would resemble those within. The data did not support this assumption. The citrate controls in silicone listed in Table IV showed a 41 and 44 per cent reduction in two cases and 27 per cent in the third where the citrate was raised to 3.8 per cent of the final mixture. In another experiment not shown, an ovalate control in plain glass gave a 40 per cent reduction. Where heparin was the only anticoagulant present at 10 units or more per cubic centimeter, the platelet fall in silicone ranged from 56 to 75 per cent in Experiment D, 81 to 90 per cent in Experiment E, and 57 to 66 per cent in Experiment F, so that the decline in all three was definitely greater than with citrate or ovalate. A plain glass surface may be considered a uniform stimulus for platelet change, and in tests with heparin Wright found a reduction of 55 per cent to over 70 per cent compared with 10 per cent in the paraffin control. We found it rather surprising, therefore, that there was not sufficient difference between plain glass and silicone vessels to justify the thought that the character of the surface is an important factor in the reduction of platelets when anticoagulants are present. This result, together with other experiences with silicone, leads to the suggestion that at the moment of mixing certain changes affecting the platelet already may have been initiated and are continued even though at a retarded rate and to a limited extent after the addition of anticoagulants.

It should be pointed out that good blood samples for the silicone technique are more difficult to obtain from dogs than from human subjects. This is emphasized by the careful experiments of Patton, Ware, and Seegers.¹² Since Wright's tests were made with human blood, the differences mentioned between her results and ours may be related to this fact. Another variable which may be involved is suggested by the work of Binkhous¹³ who has presented evidence of a plasma factor necessary for the lysis of platelets; it is not difficult to imagine agglutination as a related phenomenon. In experiments on dogs receiving

Diemaid but not recorded here, we have noted marked differences in the response of platelets from different animals to the same dose of heparin *in vitro*. It is evident, therefore, that these experiments with silicone cannot be regarded as simulating conditions within the blood vessel. Besides the changes in the blood incident to its removal, such factors as mixing and carbon dioxide tension are quite different *in vitro* compared with *in vivo*.

One of the puzzling features of the *ex vivo* experiments, illustrated in Table IV, was the return of the platelets after an initial decline when the blood mixtures were followed for twenty four hours or longer. This did not occur in all blood samples as for example, in Experiment C where the count remained consistently low from twenty four to seventy two hours. Even over shorter periods of time late samples might show increases over earlier ones as in Experiment G and occasionally even a saline control in silicone might show it as in Experiment B. Undoubtedly this was partly due to uneven distribution but the counts of red and white cells made at the same time did not show such wide variations. The decline in agglutination suggested one reason for an increase but the platelets in the aging blood could not always be recognized as old and indeed one had to consider again whether platelets can be formed from red cells.

In Schilling's "ideal" red cell a review of which is given by Ulpts¹⁴ two structures are indicated which easily may be counted as platelets, and indeed one of them was so labelled by Schilling. Occasionally the ghost of a red cell surrounding such a structure will enable one to eliminate it from the count, but it is possible that the inclusion of some of these Schilling bodies may be partly responsible for the rise of the count in late samples. But there cannot be a great many of these "ideal" erythrocytes because platelet counts made by the use of 5 per cent urea solution which hemolyzes red cells showed general agreement with platelet counts made in the usual formalin citrate mixture being sometimes lower and sometimes higher. Since the use of urea allows a dilution of only $\frac{1}{10}$ of the blood sample while the other count is made in the $\frac{1}{100}$ dilution there was a much greater chance of the former showing an increase if many erythrocytes containing Schilling bodies were present. Rees and Ecker¹ called these refractile structures Arnold bodies, and the addition of formalin to the 3.8 per cent sodium citrate which they recommended made the laking of red cells less frequent. Irregularities in platelet counts made in the $\frac{1}{100}$ dilution suggest that the red cells may interfere with a free distribution of platelets *when clumps are present* and the error is multiplied when compared with the lower dilution. For this reason reliance has been placed on the count made in the urea solution and the values given in Table VI were so obtained.

With regard to Table VI it should be pointed out that the barbiturate may have some slight influence on the figures. The effect of this type of anesthesia in lowering the erythrocyte count is well known. During 1941-1942 in some experiments that were being made at Toronto by Dr. R. E. Haist on surgical shock, one of us (D. F.) noted the usual reduction in red cells following the barbiturate but found the platelets were not reduced in the same proportion. This has the effect of a relative increase and is quite definite when compared with preanesthetic counts. There was an indication that a slight relative increase might continue for

a time in successive samples after anesthesia. This may be the reason why in Table VI some of the experiments show at thirty or sixty minutes a higher count than the initial one. We mention this as a caution in case this increase be interpreted as increased production in immediate response to the heparin. The anesthesia avoids the excitement incident to the taking of each sample in untrained dogs, and since the important count is within five minutes after heparin and is usually only a few minutes after the initial count, conditions appear more favorable for a comparison between different samples of heparin.

Platelets are sensitive to many foreign materials and it should be recalled that the synthetic anticoagulants studied by Astrup and Piper¹⁶ also caused platelet agglutination, but the fact that heparin brings about this phenomenon has the appearance of a physiologic contradiction. The formation of platelet emboli does not seem to harmonize with the prevention of platelet thrombi. However, the very act of purification may cause commercial heparin to differ from that released within the animal body. The results shown in Table VI suggest that more work is required before platelet agglutination can be accepted as a property of natural heparin.

The effect of commercial heparin on platelets resembles its effect on erythrocytes seen in studies of lipemia by Waldron and Friedman.¹⁷ It is possible that there is some common underlying factor for both these actions.

SUMMARY

Heparin on intravenous injection in man or dog may cause a brief thrombocytopenia. In dogs this may reach 10 per cent of the original count, although there is individual variability. The fall in the platelet count is repeated with repeated injections. The decline is also observed when heparin is added to blood in silicone vessels. Some experimental lots of heparin in the same dosage of anticoagulant units have shown much less effect upon platelets than the present commercial product.

The authors are greatly indebted to Dr. C. H. Best for his interest, to Miss Erica Lepp for a number of the platelet counts, to Mr. E. Nipke for the opportunity to obtain blood samples from a series of dogs receiving heparin, and to Mr. F. C. Monkhouse for the blood heparin determinations.

The aid given us by Dr. Tigo Astrup, Dr. A. M. Fisher, and Dr. A. F. Charles has been particularly appreciated.

The study was completed under a grant from the National Research Council of Canada.

THE EFFECT OF HEPARIN ON PLATELETS IN VIVO

ARMAND J. QUICK, M.D., Ph.D.,* JACOB N. SHANBERGE, M.D.,†
AND MARIO STEFANINI, M.D.‡
MILWAUKEE, WIS.

WHEN either peptone or anaphylactic shock is produced in dogs, the platelets are temporarily but precipitously diminished, heparin is liberated into the blood, and histamine or a histamine-like substance is produced.¹ This triad has become of particular interest since Allen and Jacobson² have found that dogs exposed to highly ionized radiation suffer a marked thrombocytopenia, heparinemia, and a peripheral capillary dysfunction manifested by petechiae. In a recent note Copley³ implies that the heparin is responsible for the thrombocytopenia and that it "may also take part in the formation of the petechial hemorrhages." He cites his work and that of his associates in which it was shown that heparin causes an agglutination *in vitro*⁴ and likewise an agglutination and subsequent thrombocytopenia *in vivo*.⁵ As the result of these observations it becomes important to determine whether heparinemia produced either endogenously or exogenously causes thrombocytopenia, or whether the fall in platelets and the outpouring of heparin in shock and after high ionizing radiation are concomitant occurrences resulting perhaps from a common agent. As a preliminary approach to this problem, the effect of intravenously administered heparin on the number of circulating platelets was studied.⁶

EXPERIMENTAL

The action of heparin on the platelet count was determined in rabbits, dogs, and men. The heparin employed was obtained from several pharmaceutical companies in the form of 10 c.c. vials each containing 100 mg. of the sodium salt of heparin. Several of these preparations have their potency stated in terms of Toronto units (1 mg. of the sodium salt of heparin is equivalent to 110 units).⁷

The heparin was injected intravenously at a constant slow rate of approximately 1 to 2 c.c. per minute. In man only one standard dose was studied, namely 0.8 mg. (88 Toronto units) per kilogram of body weight, since this approximates the one generally employed for prophylaxis against thrombosis. In dogs and rabbits the doses ranged from 0.5 to 5 mg. (55 to 550 units) per kilogram of body weight. Samples of blood were taken before and at fixed intervals after the heparin was given. The vein into which the heparin was injected was not

§After this investigation was completed we were informed by Dr. Charles H. Best that Dr. Edward Fidler and Dr. Louis Jaques had made a similar study. Dr. Fidler kindly supplied us with a summary of their findings which are similar to ours. They too observed the rapid agglutination of platelets in dogs following the injection of heparin. See p. 1410.

¶We are indebted to Dr. K. K. Chen of Eli Lilly & Company, Indianapolis, Ind.; Dr. John T. Correll of The Upjohn Company, Kalamazoo, Mich.; Dr. George R. Hazel of the Abbott Laboratories, North Chicago, Ill.; Dr. Merton Lockhart of Lederle Laboratories, Inc., New York, N. Y.; and Dr. Kenneth W. Thompson of Roche-Organon, Inc., Nutley, N. J., who kindly supplied us with vials of heparin from their respective companies.

used for subsequent collection of blood. A silicone coated syringe was used and the blood for the platelet count was transferred immediately to a silicone coated test tube immersed in ice water. An alternative method consisted of placing 0.2 cc of 3.8 per cent sodium citrate directly in a 1 cc syringe and drawing blood exactly to the mark. The platelets were determined by direct count. The blood was diluted 1:200 with 3.8 per cent sodium citrate containing 0.2 cc formaldehyde (40 per cent) per 100 cubic centimeters.

In man the change in heparin concentration can be successfully followed by the coagulation time (Lee White), the prothrombin time and the thrombin titration.⁶ In rabbits and dogs only the last method is satisfactory since the prothrombin time is too little affected and the coagulation time is so markedly prolonged that it becomes impractical to perform and it is difficult to achieve accuracy.

RESULTS

The findings obtained by injecting heparin into man are given in Table I. It will be observed that the platelet count remained unaltered and that all of the heparin was removed from the blood in three to four hours. The bleeding time remained normal even during the time the heparin concentration in the blood was highest.

Hoffman La Roche. Each subject received 0.8 mg of heparin per kilogram of body weight.

†The thrombin was prepared according to the directions of Eagle and modified by Quick.⁷ The product obtained which is designated as full strength (F S) will clot two parts of oxalated human plasma in three seconds. When the thrombin is diluted 1:5 (1/5 S) it clots plasma in seven seconds.

In Table II the effect of intravenously injected heparin on dogs is recorded. It will be observed that the five brands of heparin had approximately the same effect in reducing the number of circulating platelets. A dose of 0.5 mg (55 units) per kilogram of body weight seems to be the critical amount since at some times produced thrombocytopenia and sometimes did not. Above this dose, a fall in platelets unfailingly was observed.

To determine how soon the platelets are affected after the injection of heparin blood was taken every minute for five minutes. One minute after the injection all the platelets were clumped but still in the blood stream. A minute later single platelets again appeared and the clumps were diminishing. At the end of five minutes all agglutinated platelets had disappeared from the blood (Table III).

The various brands of heparin produced no thrombocytopenia in rabbits as seen in Table IV. The platelet counts were made on arterial blood.

Only a few studies of the effect of injecting peptone in rabbits were made since they yielded results similar to the ones obtained earlier by Quick, Ott and Baronofsky. Peptone causes a marked drop in the platelet count but produces little or no heparinemia (Table V) whereas in dogs enough heparin is often poured into the blood to render it uncoagulable.

From the results obtained in the present study one can conclude that the intravenous injection of heparin in doses as large as 5 mg. per kilogram of body weight in rabbits and 0.8 mg. in man causes no demonstrable diminution of the circulating platelets. In dogs, on the contrary, doses as small as 0.5 mg. per kilogram of body weight may cause a marked but transient fall in the platelet count. This is due to the agglutination of these cells and presumably to the subsequent removal of these clumps by the capillary bed. The agglutination as shown in Table III occurs almost immediately after the heparin is injected. Promptly following this reaction restoration of the platelet count begins to occur and may be amazingly rapid. In some instances the count may be one third of the original level five minutes after the injection and completely normal ten minutes later.

Since heparin does not cause thrombocytopenia in either man or rabbit it is clear that this agent per se has no influence on platelets. To imply that the thrombocytopenia following high ionizing irradiation is the resultant of heparinemia is certainly open to question. To be sure the injection of peptone in dogs causes heparinemia, thrombocytopenia, and histamine production but in the rabbit the same dose of peptone produces only thrombocytopenia. It is unlikely that the heparinemia in dogs is the cause of the abrupt drop of platelets. It might also be stated that injection of histamine likewise causes no change in the platelet count⁷ consequently this agent can not be implicated in the thrombocytopenia observed in shock. On the basis of present evidence it seems reasonable to conclude that the three effects of shock seen in dogs are independent of each other except that their causative agent may perhaps be the same. One must not ignore the possibility however that the coagulation defect which we have recently demonstrated in thrombocytopenia⁹ when accentuated by heparinemia may convert the vascular hyperpermeability due to histamine into a serious hemorrhagic condition. It is doubtful if heparin alone or even in the sole presence of a thrombocytopenia will cause petechiae or a prolonged bleeding time. These later effects assuredly are the result of a vascular factor.

It is curious that heparin causes a thrombocytopenia in dogs but not in man or rabbits. One can proffer several possible explanations. The first is that the purified heparin may still contain a trace of impurity to which the dog but not the rabbit or man is susceptible. A second hypothesis is that heparin reacts with a plasma constituent, thereby producing an agent which causes the agglutination of platelets. According to this view dog plasma contains this factor but rabbit and human plasma do not. A third hypothesis is that dog plasma lacks protective factors that would counteract the physicochemical alteration induced by heparin. It is to be noted that the effect of heparin on the platelets is immediate and that the platelets actually begin to increase while the heparinemia is still at its height. This shows that the presence of even a high concentration of heparin does not depress the platelet count but actually allows a rapid restoration which is brought about very likely from the liberation of the individual cells from the agglutinated clumps.

There are probably two types of platelet agglutination. The first is the type induced by heparin in dogs by peptone and perhaps by many other agents as Achard and Aynaud noted as early as 1908¹⁰. Perhaps this type of agglutination is brought about by as simple a change as the removal of an electric charge needed to maintain the discreteness of the platelet. The second type of agglutination is apparently the result of labilization of the platelet by thrombin. In this type the platelets become sticky, readily adhere to rough surfaces, and disintegrate thereby liberating an enzyme that activates the plasma thromboplastinogen. The platelets remain stable whenever the production of thrombin is inhibited. This accounts for the stability of platelets in hemophilia, in mailed Dicumarol hypoprothrombinemia, in oxalated and citrated plasma and in heparinized plasma. Heparin however does not prevent the first type of agglutination as Quick, Ota and Baronofsky⁷ and Fridlar and Waters¹¹ have shown.

From a practical point of view the agglutination of platelets by heparin is of little moment since it does not occur in man and since even in dogs it is very transitory and unaccompanied by any untoward effects. Heparin depresses platelet agglutination of the second type by inhibiting the formation of thrombin as well as by neutralizing it. Because of this action, heparin is a reliable drug for prophylaxis against intravascular clotting.

SUMMARY

The effect of intravenously administered heparin on the circulating platelets was studied in man, rabbits, and dogs. Five brands of commercial heparin were used. No significant agglutination or thrombocytopenia was observed in man.

and rabbits even after relatively large doses. In dogs a dose of 1 mg per kilogram of body weight invariably caused agglutination of platelets and a subsequent transitory thrombocytopenia. Probable causes for this are discussed.

EFFECT OF VITAMIN K ON DICUMAROL INDUCED HYPOPROTHROMBINEMIA IN RATS

E J BOYD M D AND E D WARNER M D
IOWA CITY IOWA

MOST of the reports dealing with the effect of vitamin K on dicumarol induced hypoprothrombinemia have been based on one or another of the one stage methods of prothrombin estimation¹. It has been shown that these methods depend not only on the concentration of prothrombin but also on the rate of conversion of prothrombin to thrombin². Thus the one stage tests lose some of their reliability as a means of measuring prothrombin concentration unless factors which may influence conversion rate are eliminated. In recent years several workers have established that another constituent present in normal plasma influences the conversion of prothrombin to thrombin^{3,13}. In addition the presence of a distinct inhibiting substance in the blood of animals treated with a hydrogenated derivative of Dicumarol has been postulated^{14,1}. This substance is considered to be similar to but not identical with heparin. Some of the clinical reports are based on the cessation of spontaneous bleeding which is admittedly influenced by many variables.

The two stage method of prothrombin determination¹⁰ separates the conversion phase from the clotting phase and thereby eliminates the rate of conversion of prothrombin to thrombin as a factor in prothrombin measurement. It seems pertinent, then to examine by this method the effect of Dicumarol on the prothrombin level of blood and the modification of that effect by vitamin K.

MATERIALS AND METHODS

Adult albino rats of the Sprague Dawley strain were used. They were maintained on a diet which contained adequate amounts of vitamin K. Water and diet were fed ad libitum.

Suspensions of 3,3 methylenebis (4 hydroxycoumarin) were prepared as follows: 70.2 mg Dicumarol† were suspended in 32.1 cc of distilled water. To effect increased dispersion of the drug suspension 3.0 cc of 0.1N sodium hydroxide were added.

Menadione‡ (2 methyl 1,4 naphthoquinone) was dissolved in corn oil (Mazola) so that 50 mg were contained in each cubic centimeter of the solution.

Hykinone§ (menadione bisulfite) was used as supplied by the manufacturer. One cubic centimeter contains the equivalent of 2.5 mg. of menadione.

Dicumarol and menadione were given by stomach tube and Hykinone was given by intraperitoneal injection. Both the vitamin K preparations and Dicumarol were given as daily doses.

Blood obtained by jugular puncture was drawn into 1.8% per cent potassium oxalate. The blood and anticoagulant were carefully mixed and placed in a hematocrit tube and the tube was set in ice water to induce rapid cooling. After centrifugation in a refrigerated room (5°C) prothrombin titration by the two stage method¹⁰ was performed on the plasma.

RESULTS

I *Dicumarol Alone*—A In the first experiment the animals were given daily doses of constant size of Dicumarol, and the prothrombin level (expressed in per cent of normal) was followed for a period of from two weeks in some

Fig 1 —The effect of daily doses of Dicumarol on the prothrombin level of rat plasma

Fig 2 —The effect of daily doses of increasing size on prothrombin level of rat plasma.

cases to as long as forty-three days in others. Fig 1 shows a typical curve. There was a definite tendency for the animals to develop a tolerance to the drug. After approximately two weeks the prothrombin level tended to rise, and at the end of three to four weeks it commonly approached normal values. The daily variations in prothrombin level of Dicumarol-treated rats were great, as much

as 40 per cent in some instances. These variations are greater than can be explained on the basis of technical error in performing the determinations. Repeated determinations on many occasions showed that the variations in prothrombin level were genuine.

Fig 3—A Single dose of 4 mg Dicumarol
B Single dose of 4 mg Dicumarol and 4 cc Hykinone

Fig 4—The effect of Hykinone given during administration of Dicumarol

B In another group of rats the dosage was gradually increased in an effort to keep the prothrombin at a low level. Virtually the same type of curve was obtained (Fig 2) although the prothrombin level tended to remain low for a longer time. Succeeding large doses had less effect than earlier small doses.

C In the third experiment the effect of a single dose of Dicumarol was studied (Fig 3, A) A dose of 40 mg of Dicumarol was given, and the prothrombin level was followed for two days after it had returned to normal The maximum hypoprothrombinemic effect was obtained within forty eight hours and recovery was complete within ninety-six hours after the time of medication

In the foregoing experiments the prothrombin level promptly returned to normal when Dicumarol administration was stopped This occurred within ninety-six hours after administration of the last dose of Dicumarol Recovery after repeated doses was at essentially the same rate as after a single dose

Fig 5—A Left-hand curve The effect of menadione given immediately preceding discontinuance of Dicumarol on the rate of recovery from the Dicumarol effect.
B, Right-hand curve Menadione preceding during and after Dicumarol administration

II *Dicumarol and Vitamin K*—A Hykinone (40 cc) had no detectable effect when given to rats receiving daily doses of Dicumarol (Fig 4) No change was observed which was greater or in a different direction than frequently was observed with continued administration of Dicumarol alone

B In a second group of animals large doses of menadione (50 mg daily) were given for a period of one to two weeks before Dicumarol administration was begun, and it was continued during the period of Dicumarol administration (Fig 5, B) A standard dose of 20 mg of Dicumarol was given The hypoprothrombinemic effect of the Dicumarol in these animals was similar to that in animals which had received no menadione (Fig 1) Upon discontinuing the Dicumarol, recovery occurred at the same rate as in rats which had received no menadione

C A third group of animals was given Dicumarol for at least five and as long as twenty-four days During the last three to six days of Dicumarol administration 50 mg of menadione were also given (Fig 5, A) When both

Dicumarol and menadione were stopped the prothrombin level rose to normal at the same rate as it did when the administration of Dicumarol was stopped in animals which had received no menadione (Fig 6) In other animals in the

Fig 6—Rate of recovery from Dicumarol effect after drug was stopped

Fig 7—Rate of recovery from Dicumarol effect when Hykinone was given after the Dicumarol was stopped. Note that the prothrombin was reduced when Dicumarol was given again in spite of the continued administration of Hykinone.

same experiment vitamin K was given as Hykinone (dose equivalent to 10 mg menadione) intraperitoneally. The results were the same as with menadione in corn oil by stomach tube.

D In a fourth group of animals, Dicumarol was given for a period of five to ten days and then followed by the administration of 40 c.c. of Hykinone daily during the period of recovery (Fig 7). Recovery occurred at the same rate and to the same degree as in rats which received no Hykinone (Fig 6). When Dicumarol was administered immediately following complete recovery a response similar to that obtained with the initial dose was observed in both groups.

E In single dose experiments the prothrombin curves of rats given Dicumarol and Hykinone together (Fig 3, B) were similar to those of rats which received Dicumarol alone (Fig 3, A).

DISCUSSION

There are two outstanding differences in technique between these experiments and those reported by Overman and co-workers.² Their animals were given a diet low in vitamin K while ours were given a diet which contained adequate amounts of it. The prothrombin determinations in their experiments were done by a one stage method using dilute plasma while ours were done by the two-stage method. We wished to parallel as closely as possible clinical conditions in which the diet is not likely to be deficient in vitamin K, and to measure prothrombin concentration only.

The results of clinical studies of the effect of vitamin K on Dicumarol induced hypoprothrombinemia are confused somewhat because additional measures such as discontinuance of Dicumarol administration, blood transfusions, and other agents have been used to correct the hemorrhagic tendency. The clinical studies also lack the control possible in experimental animals. In many cases vitamin K was given at a time when the prothrombin level might have been expected to be rising due to the development of tolerance to the drug. Another possible cause for the great variation in clinical results is the wide diversity of methods used to estimate prothrombin. These vary from simple observation of cessation of spontaneous bleeding to the dilute plasma technique of Link. There is some evidence¹⁷ that the Quick and Link methods cannot be substituted for each other. This suggests that they may measure different things. They, as all the one-stage methods, are certain to be influenced by plasma factors other than prothrombin concentration. There is also evidence¹⁸ that the dilute plasma techniques have much greater standard deviations on duplicate determination than do whole plasma techniques. Even though the sensitivity is increased by dilution of the plasma, the increased possibility for error may be another reason for inconsistencies of results.

It is possible that vitamin K administration affects factors which govern prothrombin conversion as well as those which control its concentration. This could explain the protective action of vitamin K against Dicumarol which has been reported by workers using the one-stage methods of prothrombin estimation. It would also explain why this action is not demonstrable by the two stage method.

SUMMARY

1 The prothrombin level, as determined by the two stage method, varied considerably from day to day in rats treated with Dicumarol. There was a

definite recovery phase soon after the initial fall in prothrombin caused by Dicumarol. Later the animals showed a decided tendency to escape from the effect of the drug.

2 Menadione and menadione bisulfite in large doses had no detectable counteracting effect on the prothrombin level of rats whether given before, during, or after Dicumarol administration.

VENTRICULAR IRREGULARITIES INDUCED BY SYMPATHO-ADRENAL DISCHARGE AND CHLOROFORM

GEORGE X. TRIMBLE, A B, M D
COLUMBIA, Mo

CHENOWETH,¹ working with dogs, reported that the inhalation of the vapor of various lipotropic hydrocarbons including toluene, xylene, petroleum ether, and gasoline, sensitizes the mammalian ventricle to epinephrine with resultant extrasystoles, tachycardia and fibrillation, simulating the well known chloroform-epinephrine syndrome.^{2 3 4 5}

In discussing his findings, Chenoweth suggests that human subjects sensitized by the inhalation of such vapors might be susceptible to ventricular fibrillation, if subjected to emotional stress which would liberate epinephrine.

The electrocardiographic studies presented here, on dogs in which a sympatho-adrenal discharge was pharmacologically induced and to which chloroform was administered during the height of such induction, seem to substantiate that suggestion.

Dogs weighing 2 to 15 kilograms were put under basal anesthesia by intraperitoneal injections of sodium pentobarbital solution carrying 37.5 mg per kilogram of body weight. Control presurgical electrocardiographic records were then taken using the three standard leads. Tracheal and carotid cannulae were then inserted and the femoral vein was exposed, and after a thirty minute rest period following the surgery, an electrocardiographic Lead II was recorded. Each animal was given from 0.5 to 2.0 mg of atropine sulfate intravenously, depending on the weight of the animal, and five minutes later 15 mg of physostigmine saheylate. Control records (electrocardiographic Lead II) were taken three minutes after each drug injection. Five minutes after the physostigmine was given, 0.2 to 4.0 mg of acetylcholine bromide (depending on the weight of the animal) were injected. At the onset of the resulting blood pressure rise, the administration of chloroform vapor was begun and continued uninterruptedly until a danger point as indicated by marked fall in blood pressure and apnoea was reached. Continuous electrocardiographic Lead II, blood pressure and respiration records were obtained from the time just prior to the acetylcholine administration until the cessation of the chloroform anesthesia.

In this sequence of injections, presumably the muscarinic action of the acetylcholine would be blocked by the atropine and the destructive action of cholinesterase on the acetylcholine held in check by the physostigmine, leaving the nicotinic action of the acetylcholine unrestrained. The nicotinic effects of acetylcholine are believed to include a sympatho-adrenal discharge and the mobilization of epinephrine or an epinephrine-like substance.^{6, 7, 8} If the nicotinic

From the Departments of Internal Medicine and Physiology School of Medicine University of Missouri

Received for publication Aug 31 1948

effect were great enough, it seemed that the intrinsic epinephrine liberated by the animal could affect the chloroform sensitized ventricular complex just as intravenous injections of epinephrine

Nine dogs of both sexes and various weights were studied. No differences in results attributable to sex or weight were found. There was however a wide variation in sensitivity as indicated by the fact that in three dogs a nicotine effect could not be induced, in spite of different dosages of drug administration.

In the six dogs in which nicotine responses were evoked the following abnormal electrocardiographic findings were obtained during the reaction to chloroform

- Three dogs Ventricular extrasystoles varying from single extra beats to short bursts of twenty or more ventricular extrasystoles
- Two dogs A persistent ventricular tachycardia of several minutes duration
- One dog A ventricular tachycardia changing to fibrillation during which the animal expired

In all instances except the last the normal electrocardiographic pattern returned following the termination of the abnormal cardiac activity.

Aside from the changes listed no other deviations in the electrocardiogram were noted and these changes occurred only during chloroform inhalation following the injections of atropine, physostigmine and acetylcholine. No such changes in electrocardiogram were noted following the injections of atropine, physostigmine, and acetylcholine into animals receiving no chloroform.

This was to be expected, for Myerson and co-workers⁹ have shown that although physostigmine and choline ester may produce severe heart block atropine prevents this block. In the present experiments atropine and physostigmine always preceded the injection of the acetylcholine.

The findings reported here strengthen the suggestion of Chenoweth¹ that intrinsic epinephrine if liberated in sufficient quantity through emotional stress could present a serious hazard through its effect on the ventricular complex sensitized to various hypotonic hydrocarbons.

LABORATORY METHODS

A MICROMETHOD FOR THE DETERMINATION OF THE HUMAN ALBUMIN, GLOBULIN, AND HEMOGLOBIN CONTENTS

BACON F CHOW, PH D, LOIS HALL, BS, B J DUFFY, MD,
AND CARL ALPER, PH D
NEW BRUNSWICK, N J

IN OUR previous communications^{1, 2} it was reported that the estimation of human albumin in serum or other body fluids by means of the precipitin reaction gives an accuracy which approximates that of electrophoretic analysis, the generally accepted standard, and requires only a minute amount of the protein. This latter situation makes it possible for the development of a micromethod for the determination of albumin, total protein, and hemoglobin in capillary blood taken by finger puncture. These determinations were performed with 0.2 ml of blood which was then diluted with a known volume of 0.85 per cent saline solution, containing enough heparin to prevent coagulation. The red cells were then removed by centrifugation and laked with a dilute ammonia solution for hemoglobin determination with a photoelectric colorimeter. Aliquot samples of the supernatant were used for determination of total protein nitrogen and albumin nitrogen. The former was estimated by measuring the turbidity of the trichloroacetic acid precipitate, the latter, by the precipitin method. The difference between the total protein nitrogen and albumin nitrogen was taken as the total globulin nitrogen.

Reagents —

1 A dilute ammonia solution. Approximately 5 ml of concentrated ammonia solution (28 per cent ammonia by weight) are diluted with water and made to 1 liter.

2 A 7.5 per cent trichloroacetic acid solution. Seventy-five grams of Merck's reagent grade trichloroacetic acid are dissolved with water and made to 1 liter.

3 A normal saline solution, 17.0 grams of chemically pure NaCl are dissolved with water and then made to a volume of 2 liters. To one liter of this solution are added 10 mg of heparin.

4 Antihuman albumin rabbit serum. Sera of rabbits immunized against human albumin can be prepared according to our previously described procedure¹. The pooled sera is kept in a frozen state until shortly before use, and filtered if necessary, after thawing. It is then diluted exactly with an equal volume of the saline solution.

Procedure —

Blood is drawn from the tip of the finger by puncturing with a dry lancet until it flows freely. A 0.20 ml sample is measured with a capillary pipette and transferred quantitatively into a 15 ml centrifuge tube containing 10.0 ml of 0.85 per cent saline solution with heparin. The suspension is then centrifuged for fifteen minutes, and the supernatant (referred to as SU) is carefully removed by a capillary tube and saved for the determination of the albumin nitrogen, and the total plasma protein nitrogen.

From the Nutrition Department of Development Division of E. R. Squibb & Son, New Brunswick, N. J. and the Sloan Kettering Institute for Cancer Research, New York, N. Y.
Received for publication Sept. 13, 1945.

Determination of Hemoglobin —

The red cells at the bottom of the tube are hemolyzed with 5 ml of the dilute ammonia solution. After taking 4 ml of the hemoglobin solution are then pipetted into a Klett Summerson tube containing 4 ml of the same ammonia water. Thus the final sample contains an equivalent of 0.0133 ml of blood. The amount of hemoglobin is then determined colorimetrically, using a green filter of 540 millimicrons. To express the results in grams per cent (see columns A and B in Table I) it is necessary to determine the oxyhemoglobin factor by correlating the colorimeter readings with oxygen combining capacity.

Determination of Total Protein Nitrogen —

Duplicate samples of 3.0 ml of the supernatant (S.U.) is pipetted into two Klett Summerson tubes to each of which are then added 2.0 ml of 1 per cent trichloroacetic acid solution from a 10 ml burette. The turbidity produced is then measured in a Klett Summerson

Fig 1 — A standard curve showing the relationship between turbidity readings and micrograms of serum protein nitrogen

tube after standing at least five minutes. The readings remain constant for more than two hours after precipitation. The amount of protein in the precipitates can then be estimated from a previously standardized curve which is obtained by measuring the turbidity of the trichloroacetic acid precipitate of a known amount of serum protein nitrogen. The results of a typical experiment are plotted in Fig 1. To substantiate that such a relationship is applicable to normal as well as abnormal serum we have compared the Kjeldahl nitrogen with the turbidity nitrogen.

Determination of factor Procure sample of fresh blood and determine oxyhemoglobin content by either the oxygen capacity or the carbon monoxide capacity method. Run a colorimetric determination on duplicate or triplicate 0.0 ml portions of this blood. From the known hemoglobin content of the blood the factor may be determined as follows:

$$\frac{\text{Gm per cent hemoglobin}}{\text{Colorimeter reading}} = \text{Oxyhemoglobin factor}$$

The data (see Table II) are separated into four groups according to the percentage of albumin in the serum, ranging from 31 to 70 per cent. The amount of total serum nitrogen in each sample as determined by the Kjeldahl method is arbitrarily taken as 100 per cent with which the turbidity nitrogen is compared. The results demonstrate that the turbidity method gives a slightly higher result of less than 10 per cent and a standard deviation of about 5. Such an agreement between the two methods may be considered as satisfactory for clinical use. The results of a typical experiment with variations of the individual samples are recorded in columns C, D and E in Table I.

Determination of Albumin Nitrogen—

The amount of human albumin nitrogen in the supernatant (SU) is determined immunologically according to the procedure previously described. The following modifications are introduced in order to adapt this method to the small size of sample obtained by finger puncture. Two milliliters of the supernatant (SU) are diluted with an equal volume of 0.85 per cent NaCl solution. Two 1 ml samples of this solution are equivalent to 0.0018 ml of the original blood, are then added to two Klett Summerson tubes for high rate determinations. Four milliliters of the diluted antihuman albumin rabbit serum are added to each tube from a 50 ml burette, and the turbidity of the immune precipitate is measured after standing at room temperature for at least thirty minutes with a Klett Summerson photoelectric colorimeter using a blue filter of a wave length 420.

TABLE II DETERMINATION OF THE TOTAL PLASMA PROTEIN NITROGEN BY PRECIPITATION WITH TRICHLOROACETIC ACID

PER CENT OF ALBUMIN IN PLASMA	NUMBER OF SAMPLES	TOTAL PLASMA PROTEIN NITROGEN BY TURBIDITY METHOD*		
		%	±	S.D.
31.40	6	103	±	6.0
41.50	23	107	±	4.0
51.60	17	106	±	5.0
61.70	5	107	±	5.1

S.D. Standard deviation

* Expressed as per cent of that found by the Kjeldahl method which is taken as 100 per cent

The amount of human albumin corresponding to the turbidity readings can be estimated from the standard curve. Multiplying the albumin content per sample (column G in Table I) by the serum dilution (i.e. 51×2 equals 102) gives the total albumin nitrogen per milliliter of blood (column H). The ratio of total albumin nitrogen to the total nitrogen as determined either with the micro Kjeldahl method (column I) or from the turbidity of the trichloroacetic acid precipitate (column J), multiplied by 100 gives the per cent of the total nitrogen as albumin. The difference between 100 per cent and the per cent of albumin nitrogen gives the per cent of globulins (column K).

Results—

The results of a typical experiment with samples of blood drawn from thirteen individuals are summarized in Table I, in order to show the normal variations of routine determinations. They demonstrate that the agreement in total plasma protein nitrogen between the two methods (micro Kjeldahl and turbidity) is satisfactory for clinical use. The average percentage deviation of the turbidity nitrogen from the Kjeldahl nitrogen is 2.6 per cent. The same magnitude of deviation is reflected in the calculation of per cent of albumin based on total protein nitrogen measured with either one of the two methods. The average percentage albumin in the plasma of this group of individuals is only 37 per cent.

In Table III are summarized our data from thirty eight normal individuals. Similar results obtained by other leading methods are included for comparison. It can be noted that the average concentration of both hemoglobin and of plasma proteins in grams per 100 ml of blood of our normal individuals is higher than that reported in the literature. Whether this difference can be attributed to the difference in the method of determination, or to the individual variation, is hard to decide on the basis of our limited number of experiments. Our average figures in the per cent of albumin in plasma approximate closely the reported figures of electrophoretic albumin,³ but are significantly lower than those of methanol soluble albumin of Pillemer.

TABLE III SUMMARY OF DATA FROM NORMAL MEN ON HEMOGLOBIN, PLASMA PROTEINS, AND PER CENT ALBUMIN OBTAINED BY DIFFERENT METHODS

SUBSTANCE DETERMINED	METHODS USED	
	AS PRESENTED IN THIS PAPER	OTHER METHODS

5 The immunologic method for the estimation of human albumin where the total nitrogen is determined by the turbidity method.

Comparison of Albumin Content in Venous and Capillary Blood—

Although capillary blood may, under normal conditions, be used for the estimation of blood proteins, including hemoglobin and plasma, it may not serve as a representative sample of circulating blood in conditions of severe shock or in gross generalized edema. The former situation may cause the capillary to contain 30 to 40 per cent more cells and hemoglobin than the venous or arterial blood, and in the latter situation the edema fluid from subcutaneous tissue would exude with the blood from a puncture. It is believed that proper technique of finger or ear lobe puncture will minimize such errors.

In Table IV are collected the results on the comparison of per cent of albumin in plasma of capillary or venous blood of forty-three patients with various diseases, chiefly with malignant growth. In the tabulation of results it is arbitrarily assumed that the per cent of albumin in the plasma of the venous blood is 100, with which the albumin in the plasma of capillary blood is compared. The data are segregated into three groups of ascending per cent of albumin. The results demonstrate that the per cent albumin in the plasma of the capillary blood and the per cent in the plasma of venous blood agree with each other within the accuracy of the determination.

TABLE IV COMPARISON OF PER CENT OF ALBUMIN IN THE PLASMA OF CAPILLARY AND VENOUS BLOODS

PER CENT ALBUMIN	NUMBER OF SAMPLES	AVERAGE PER CENT ALBUMIN IN CAPILLARY BLOOD
30-35	3	34
36-45	26	36
46-55	14	102

The per cent of albumin in the venous blood is taken as 100 with which the per cent of albumin in the capillary blood is compared

DISCUSSION

The pathologic conditions which can affect the plasma protein concentration and different types of anemia and polycythemia which can affect blood hemoglobin concentrations have been most adequately summarized by Kagan⁴ and Philips and associates. Hence, these will not be discussed in this report. It is generally agreed that so far as the determination of plasma protein concentration is concerned, an abnormal value is a definite proof that one of the physiologic conditions controlling the concentration has been disturbed. However a normal concentration cannot be regarded as an absence of any disturbed factor since determination of plasma protein concentration does not take into account a hemoconcentration or dilution.

It has been demonstrated that in animals⁵ as well as in man⁶ an outstanding change in plasma protein as a result of protein depletion due to either inadequate vitamin⁷ protein or calorie intake or owing to a variety of diseases is a decrease in the albumin content even though the total plasma protein concentration may appear normal. It is therefore believed^{8, 9} that the determination of the per cent albumin in plasma is of greater clinical significance than any change of plasma concentration. A procedure such as that we have just described should be useful not only for diagnostic purposes but also for field studies or public health work since it permits a rapid and accurate determination with a relatively small amount of sample.

SUMMARY

A micromethod is described for the determination of hemoglobin, total plasma proteins, and albumin with 0.2 ml of capillary blood drawn by finger puncture. Blood is diluted with 0.85 per cent NaCl solution containing heparin. The suspension is centrifuged to remove red cells which are hemolyzed for the determination of its hemoglobin content by means of photoelectric colorimeter. The total protein nitrogen in the supernatant is estimated by measuring the turbidity of the trichloroacetic acid precipitate. The albumin nitrogen in the supernatant is determined immunologically. The difference between the total nitrogen and albumin nitrogen is taken as globulin nitrogen.

COLD HEMAGGLUTININ TEST BY A SLIDE METHOD

NAI CH'U CHANG, M.D. * AND TSUNG CHANG HOU, M.B.
PEIPING CHINA

THE cold hemagglutinin test recently has been widely used in the routine clinical study particularly in the diagnosis of primary atypical pneumonia. As far as we know, all previous workers have used the test tube method employed first by Landsteiner forty five years ago.¹ Recently Young² showed that the sensitivity of the test could be increased by observing the agglutination under the microscope by transferring a drop of cell suspensions to a plain glass slide. It occurred to us that the test might be performed on a hollow ground slide on which a direct microscopic examination could then be made. The results of the comparative study of the slide and the tube methods are herewith presented.

The preparation of the cell suspensions and the sera was carried out by the usual procedures described elsewhere.³ A preliminary study on the relative sensitivity of group O erythrocytes from five donors including one of us (Hou) was made first. The results of the cold hemagglutinin test with eight sera from eight patients tested with cells of these donors were found approximately the same. Thereafter Hou's cells were used in nearly all of the tests reported in this paper.

THE SLIDE METHOD

Special medicinal droppers (one drop approximately equivalent to 0.05 cc) and special microslides of 10 by 4 by 0.5 cm were used. On the surface of each slide were ten smoothly and evenly ground chambers in two rows measuring 1.5 cm in diameter and 0.2 cm in depth. In each of the ten chambers 1 drop of physiologic saline was placed and the same amount of the serum to be tested was then added to the first chamber. After the saline and the serum had been thoroughly mixed in the first chamber 1 drop of the mixture was transferred to the second chamber. Similarly twofold serial dilutions of the serum from 1:2 to 1:512 were made. No serum was added to the tenth chamber which served as a saline control. Finally 1 drop of 1 per cent cell suspensions was added to each of the ten chambers. The slide after being shaken was placed in the refrigerator at 0 to 4° C for two hours. At the end of this period the slide was taken out from the refrigerator, shaken gently and examined immediately under the microscope with a low power objective. The cell suspension showing barely visible agglutination was taken as the end point. Titers were recorded in terms of the final dilution of the serum multiplied by two. The specificity of the test was checked by the disappearance of the agglutination after the slide remained in an incubator at 37° C for one hour.

Aside from the regular slide method tests in which dilutions were first made in test tubes with pipettes and later performed on the slide were made simultaneously on sixty two specimens to determine the accuracy of the dilution by the dropper herein described. The following results were obtained. Thirty nine out of a total of sixty two specimens yielded the same titers by both methods of dilution. Except for one the specimens showed a difference in titers of not more than twofold dilution of these thirteen gave higher titers in tests with pipette dilution and nine in those with dropper dilution. The last one showed a higher titer in the test made with the dropper dilution (fourfold). It seems reasonable to conclude that the method of dilution with the dropper is accurate enough for practical use.

From the Department of Medicine, Chung Ho Hospital

Received for publication June, 1948

Present address: Department of Bacteriology and Immunology, Peiping Union Medical College

Among the workers on cold hemagglutinin test there is a general agreement that it is best to examine the serum cell mixture by the tube method after refrigeration for fourteen to eighteen hours.² Therefore during the present study many tubes and slides were examined for agglutination after one, two, three, and eighteen hours of refrigeration at 0 to 4° C. Cold hemagglutinin titers nearly always reached the maximum at two hours for the slide method and eighteen hours for the tube method.

RESULTS

During the period between May, 1946, and April, 1948, 509 blood specimens were collected from sixty-two normal individuals and 302 patients. Each of these specimens was tested according to the slide technique described. The tube test was simultaneously performed by Rose's method.³ The results obtained are summarized in Tables I and II.

TABLE I CORRELATION OF COLD HEMAGGLUTININ TITERS BY SLIDE AND TUBE METHOD

Table I shows the correlation of the cold hemagglutinin titers between the slide and the tube methods. It is obvious that the slide method is more sensitive than the tube method. There were only ninety-four (18.5 per cent) specimens whose cold hemagglutinin titers were the same by both methods, and eighteen (3.5 per cent) specimens whose cold hemagglutinin titers by slide method were

TABLE II DISTRIBUTION OF MAXIMUM TITERS OF COLD HEMAGGLUTININS BY SLIDE METHOD IN 364 SUBJECTS

CLINICAL GROUP	COLD HEMAGGLUTININ TITERS										TOTAL

Cancer	0	0	2	2	1	0	0	0	0	0	5

lower than those by the tube method. For the remaining 397 (78 per cent) specimens the slide method gave higher titers: twofold dilution 141 (27.7 per cent), fourfold dilution, 156 (30.6 per cent), eightfold dilution 76 (15 per cent), and sixteenfold dilution, 24 (4.7 per cent).

From Table II it seems clear that high titers were rare except in primary atypical pneumonia, while low titers were common in various diseases as well as in normal controls. The highest titer of cold hemagglutinins obtained in our sixty-two normal individuals was 1:64. Therefore in the present study only titers above 1:64 were considered significant.

DISCUSSION

From the foregoing study the slide method is shown to be more sensitive than the tube method. It is to be noted that the method of the cell and serum used in the present method is practically identical with that of the tube method. The difference in the sensitivity of the two methods is shown by the results presented in Table III can be explained only by the difference in the method of examining agglutination. The exact mechanism of this phenomenon is not yet clear.

Despite the sensitiveness of the slide method high titers of cold hemagglutinins were still uncommon except in primary atypical pneumonia (93.3 per cent of fifteen cases). But low titers occurred more frequently in various pathologic and normal sera. It is of some interest that 23.1 per cent of thirty-four cases of cirrhosis of the liver and 13.6 per cent of eleven cases of kala-azar showed significantly high titers of cold hemagglutinins.

SUMMARY

A slide method for the determination of cold hemagglutinin titer has been described which is not only more rapid but also simpler than the tube method. It does not require tubes and serologic pipettes. In a very small hospital laboratory it might be advantageous to escape the necessity of washing tubes and to be able to start another series of tests after merely rinsing off the slide.

reducing valve controls the pressure in the tank and therefore in the cuff during its inflated phase, this is set at around 5 pounds pressure which is above arterial cutoff but is not sufficient to cause local pressure pain

Transition from an inflated cuff to a totally deflated one and vice versa occurs in approximately one fifth second. This results in very little pooling of blood in the limb, which occurs markedly when the cuff is inflated to any point below systolic pressure for a long period of time

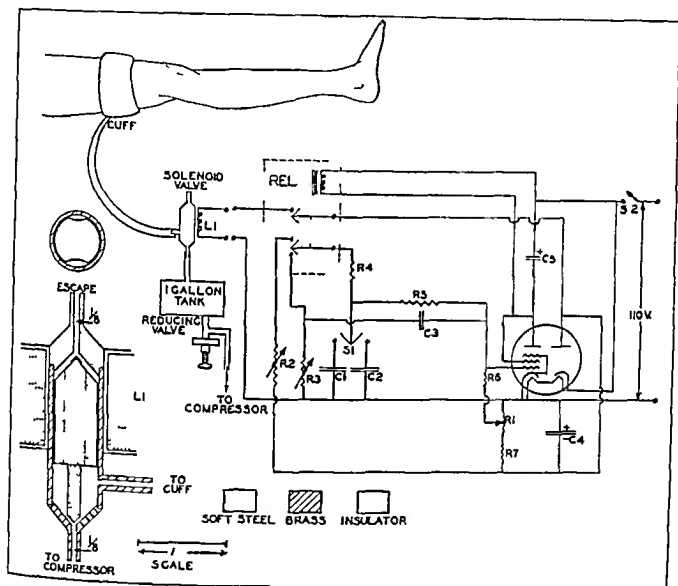

Fig 1—Electrical diagram and mechanical drawing of the apparatus for producing quantitative ischemia.

C4 and *C5* 8 mfd. 170 volt, electrolytic capacitors
 Tube 117L7/117 GT

Using this apparatus one can state in percentage the amount of time that the blood flows, and various states of ischemia can be reproduced. During the phase of blood flow there is a compensatory vasodilatation which appears to be four to six times normal. For this reason significant ischemia does not result until the period of zero blood flow is approximately 80 per cent of the cycle. When this is increased to 95 per cent severe pain ensues both in man and in

dogs Dogs in the second stage of Nembutal anesthesia will unconsciously wail loudly when this phase of ischemia is attained and will cease wailing as soon as the ischemia is lessened Such results may be repeated within narrow limits The reactions of animals to ischemia will be further analyzed in experiments designed to elucidate the cause of pain in Buerger's disease, Raynaud's disease, immersion foot, and acute poliomyelitis

FRIDAY MORNING, 9 15 A M

1 A STUDY OF PULMONARY HYPERTENSION IN CHRONIC HYPERTROPHIC PULMONARY EMPHYSEMA

CRAIG BORDEN, M.D., RUSSELL H. WILSON, M.D. AND RICHARD V. LEBERT, M.D.
MINNEAPOLIS, MINN.

(INTRODUCED BY CECIL JAMES WATSON, M.D.)

For many years the presence of pulmonary hypertension in chronic hypertrophic pulmonary emphysema has been suspected because of the occurrence of right heart failure, the presence of right ventricular hypertrophy at autopsy and electrocardiographic changes interpreted as indicative of right heart strain. Recently, the development of venous catheterization and the use of high frequency manometers have permitted the accurate measurement of pulmonary arterial pressure in patients with this disease.

In fifteen patients with chronic hypertrophic pulmonary emphysema the average pressure in the pulmonary artery was 33.9 ± 10.4 mm Hg systolic and 20.9 ± 4.7 mm Hg diastolic. This is compared with an average pressure of 90.1 ± 3.7 mm Hg systolic and 88 ± 1.5 mm Hg diastolic in twelve normal subjects. The mean cardiac index in the patients with emphysema was 3.38 ± 0.67 liters per minute and 3.59 ± 0.72 liters per minute in the normal subjects. Inasmuch as there is no reason to believe that the left auricular pressure is elevated in emphysema, this study indicates that the resistance in the pulmonary vascular bed is increased. The abnormally high intrapulmonary pressure which has been described in emphysema would account for a small portion of the rise in pulmonary arterial pressure.

A striking feature of the pulmonary arterial pressure in emphysema is the respiratory variation characterized by a marked decrease in pressure at the beginning of inspiration.

The severity of the emphysema was evaluated by measurements of vital capacity, ratio of residual air to total lung volume, pulmonary emptying rate and the degree of oxygen unsaturation of arterial blood. There was no definite correlation between the degree of pulmonary hypertension and the severity of the emphysema as estimated by these measurements. The development of pulmonary hypertension does not appear to be completely dependent upon those factors which result in the loss of pulmonary function.

Four of the fifteen patients had definite evidence of right heart failure manifested by peripheral edema, hepatomegaly and a markedly elevated venous pressure. In these four patients the degree of pulmonary hypertension was not significantly different from those without right heart failure. The development of cor pulmonale and right heart failure in pulmonary emphysema does not appear to be a consequence solely of the pulmonary hypertension but probably involves other factors such as chronic anoxia.

2 STUDIES ON CARDIORESPIRATORY FUNCTION WITH THE OXYHEMOGRAPH

BEN E GOODRICH, M D , VIVIAN G BEHRMANN, PH D (BY INVITATION), AND
FRANK W HARTMAN, M D (BY INVITATION), DETROIT, MICH

Preliminary studies with the oxyhemograph have been conducted on patients subject to varying degrees of dyspnea resulting from cardiac or respiratory disabilities. Young, apparently healthy adults also were tested.

Continuous recording of the oxygen saturation of circulating hemoglobin was afforded through the use of the oxyhemograph described by Hartman, Behrmann, and Chapman. The initial arterial oxygen saturation at rest was calculated from calibration after the patient produced a stabilized level while breathing 100 per cent oxygen. After standardization, the subjects were tested in atmospheric oxygen by simple exercises of breath holding and knee bending while supine and erect. The resultant tracings were charted for comparison using arbitrary time intervals and percentage levels.

Results of these tests reveal differences in the degree and duration of changes in arterial oxygenation in various individuals. Healthy adults, asymptomatic in daily life, varied greatly in the extent of lessened oxygenation possible by voluntary breath holding. Well adults showed moderate variation in the per cent increase in the blood oxygen saturation concomitant with exercise, although cessation of exercise uniformly resulted in an immediate depression of oxyhemoglobin to or below the atmospheric level. The return to normal was prompt. The exercise was not of a degree that exhausted the subject. In patients under similar tests exercise was not associated with increased oxyhemoglobin. Patients often exhibited marked hypoxemia with a delayed recovery. Not infrequently recovery was stamptep-like in appearance.

These findings indicate that both the degree of arterial unsaturation and the character of the recovery curve may be of clinical significance. The post exercise curve may vary as to whether recovery is spontaneous or aided by the administration of 100 per cent oxygen. Charts present typical oxyhemograms. Bronchospastic dyspnea is contrasted to structural respiratory disability. Patients with decreased cardiac reserve show abnormal curves. In these patients abnormal curves may be recorded even though symptoms are denied.

These preliminary studies indicate that the oxyhemograph together with simple tests may prove useful in the differential clinical evaluation of cardiorespiratory function.

3 THE PHYSICAL MECHANISM OF FIBROTIC REACTIONS

SILAS M EVANS, M D , AND WALTER ZEIT, PH D , MILWAUKEE, WIS

(INTRODUCED BY WILLIAM S MIDDLETON, M D)

Quartz, cholesterol, and tuberculosis produce fibrous reactions in tissue which differ quantitatively but not qualitatively in histology. This has been demonstrated experimentally by others. The symbiotic relationships between quartz and tuberculosis phospholipid have been repeatedly demonstrated.

Fibrous tissue reactions are currently considered as protective against toxins and poisons in solutions. It is pointed out that fibrous tissue is unqualified physiologically as a barrier against substances in solution. Fibrous elements are adapted to confine stress in the physical sense. In health and disease, fibrosis contributes physical support to the biologic economy.

The architecture of fibrous tissue retention conforms with Newton's equations of force. This is demonstrated by slides of biologic preparations compared with force field preparations using magnets and iron filings.

Many irreconcilable objections are recognized by those who have reviewed the solubility theory of silicosis. These are enumerated. These objections are reconcilable with another basic nonchemical mechanism.

A search for physical properties common to fibrosive materials has revealed that there is a direct relationship between the fibrosive properties of a substance and its solid state molecular symmetry. Detailed reports are in press at the present time elaborating this point.

Those substances which exist in a state of molecular asymmetry compatible with piezoelectric reactions are observed to produce fibrosis. Piezoelectricity is a mechanism whereby mechanical and electrical energy states may be converted from one to the other in either direction. A more detailed definition of piezoelectricity is presented.

One phase of our present study is presented. Barium titanate was selected because of its spectacular piezoelectric properties, its lack of solubility, and the absence of elemental silicon in its chemical makeup. The preparation of animals is described and the results obtained are presented with the use of slides and tables.

A reference is made to the scope of the present problem and reports now in press.

Conclusions — (1) Fibrosive properties and piezoelectric properties of materials introduced into tissues are directly correlated.

2 The fibrosive potential of a material selected on the basis of its physical properties alone has been demonstrated.

4 THE EFFECT OF THE ANTICOAGULANT DRUGS UPON THE CORONARY FLOW

N. C. GILBERT, M.D. AND LESTER NALEFSKI, M.D. (BY INVITATION)
CHICAGO, ILL.

During the last few years the anticoagulant drugs, heparin and Dicumarol, have been shown to have a favorable effect upon coronary occlusion. Mortality has been greatly reduced and peripheral vascular accidents have been made much less frequent through the use of these drugs. It does not seem altogether reasonable, however, that these results are due to the anticoagulant action of these drugs alone. When the case reaches the attention of the physician, the occlusion and infarct are already an accomplished fact. Anticoagulant therapy cannot alter the already formed thrombus whatever effect it might have upon future thrombotic processes. There is no definite evidence that the clot propagates or extends, except on rare occasions and there is a great deal of evidence that the clot does not propagate. It has been shown also that many instances of occlusion are initiated by a subintimal hemorrhage. According to Wartman, these latter comprise at least 18 per cent.

Our own clinical results with coronary vasodilator drugs such as aminophylline followed by oral preparations of the xanthines, closely parallel the results obtained by others with anticoagulant therapy.

In experimental work upon animals and upon the empty beating heart we have been able to show that the use of either heparin or Dicumarol increases the coronary flow volume. With heparin the effect varies from no effect to

a moderate effect, depending upon the preparation. Dicumaiol, however, has a very definite effect upon the coronary flow. The effect is equal to that of the xanthines, and apparently lasts longer. We believe that the favorable effects resulting from the use of these drugs are primarily due to their action in increasing the coronary flow.

5 CORRELATION OF ELECTROCARDIOGRAPHIC AND PATHOLOGIC FINDINGS IN INFARCTION OF THE INTERVENTRICULAR SEPTUM

GORDON B. MYERS, M.D., HOWARD A. KLEIN, M.D. (BY INVITATION), AND
TOMIHARU HIRATZKA, M.D. (BY INVITATION), DETROIT, MICH.

In a consecutive series of 161 patients with pathologically established myocardial infarction with Wilson precordial, standard and Goldberger limb leads, infarction of the interventricular septum was demonstrated in 102 patients and was accurately localized by means of coronary injection with radiopaque mass, roentgenogram, and multiple microscopic blocks. The cases were classified into three groups according to distribution of the pathologic lesion: (1) infarction largely confined to the septum, nine cases, (2) septal extension of anterior or anteroposterior infarction, sixty-nine cases, (3) septal extension of posterior infarction, twenty-four cases.

The electrocardiogram furnished suggestive or diagnostic evidence of septal infarction in all patients in group 1, in 80 per cent of group 2, and in only 33 per cent of group 3. This evidence was derived from the precordial leads in all but three instances in which it was obtained from aV_F . The standard leads were of no help. Diagnostic failures were prone to occur when the septal portion of the infarct was limited to the posterior half or to the apical third of the septum. The electrocardiographic findings were classified as follows:

1 Complete atriocventricular block due to acute posteroseptal infarct was present in two patients.

2 QRS-T abnormalities diagnostic of infarction of the anterior portion of the septum were found in eight precordial leads of forty patients. These comprised (1) right bundle branch characterized by an abnormal Q wave and/or elevated RS-T junction in $V_{1,2}$ in thirteen patients, (2) triphasic qRS complex of normal duration in $V_{1,2}$ in five patients, (3) QS complexes and upward RS-T displacement in leads over the right atrium, accompanied by abnormal Q waves in leads farther to the left, in twenty-two patients. QRS-T abnormalities in $V_{1,2}$ that were considered suggestive, but not diagnostic, of septal infarction were found in eighteen other instances. An abnormal QS or qRS complex referable to infarction of the posterior portion of the septum was recorded in lead aV_F as a result of horizontal cardiac position in seven patients.

3 Left bundle branch block was present in four instances, but was attributable to septal infarction in only one. Patterns characterized by QRS prolongation, an initial downstroke, and late intrinsicoid deflection in left axillary leads were present in ten patients, but were ascribed to subendocardial anterolateral infarction rather than the septal lesion.

4 Signs of anteroposterior infarction, considered presumptive of involvement of the intervening septum, were present in nine additional patients.

The correlation of electrocardiographic and pathologic findings will be brought out by case presentations.

6 BEDPAN DEATHS

JOHNSON MCGUIRL, M D, ROBERT GREEN M D (BY INVITATION),
 SANFORD R. COURTER M D (BY INVITATION) JEAN NOERTKER A B
 (BY INVITATION), ARNOLD GOLAUER, M D VIROIL HAUENSTEIN, M D AND
 JOHN BRAUNSTEIN, M D (BY INVITATION), CINCINNATI OHIO

The notorious frequency of sudden and unexpected deaths of patients while using bedpans in hospitals has been commented upon for many years

In an attempt to discover the factors responsible for such deaths the autopsy protocols and clinical records of patients in the Cincinnati General Hospital who died on bedpans and were autopsied have been reviewed for the ten year period from 1936 to 1946, inclusive

A second approach to the problem of determining the causes of death in such cases has been the measurement of alterations in circulatory dynamics accompanying simulated efforts of normal individuals and patients with organic heart disease to move the bowels

The precise mechanism of death in the twelve cases examined at post mortem (all with organic heart disease) was determined in only three instances (1) ruptured aortic valve (2) pulmonary embolism (3) ruptured dissecting aneurysm

Intravascular pressures measured by strain gauges and graphically recorded in normal subjects and patients demonstrated marked rises of pressure during the initial phase of bearing down within the femoral artery left ventricle pulmonary artery, right ventricle right auricle and peripheral veins Toward the end of the strain a fall in blood pressure occurred subsequently a marked rise of pressure developed

Electrocardiographic tracings in twenty five normal subjects during strain showed first bradycardia then marked tachycardia Following cessation of strain, marked bradycardia developed Migration of the pacemaker and premature contractions occasionally were noted Patients with organic cardiovascular disease showed few such changes

Since the cause of death frequently is not found at autopsy it is believed that cardiac arrhythmias or cardiac standstill may be the usual cause of bedpan deaths

Measures to combat such deaths are suggested

7 EMETINE THERAPY IN THE PRESENCE OF HEART DISEASE

W A SODEMAN M D NEW ORLEANS LA

Electrocardiographic changes occur in 25 to 50 per cent of patients with normal hearts under emetine therapy and the drug is generally considered contraindicated in the presence of heart disease We have studied eight patients in whom advanced heart disease was present and to whom emetine was administered because hepatic amebiasis was a greater threat to life than was the heart disease In five closed drainage also was performed All were at bed rest Five had arteriosclerotic heart disease, two being at the time under digitalis therapy One had in addition, hypertension and known previous congestive heart failure One had congenital heart disease with interventricular septal defect and bundle branch block, another rheumatic heart disease with mitral stenosis Six showed abnormal electrocardiograms before emetine therapy was started Under a controlled regimen of treatment with emetine dosage based upon body weight (1 mg per kilogram body weight daily not to exceed ten days) none of the pa-

tients developed symptoms or signs of heart failure. Only one showed additional electrocardiographic changes attributable to emetine. One death occurred three months and another one year following therapy, both from other known causes. In all patients the amebiasis was effectively controlled.

Despite usual warnings that emetine should not be administered to cardiac patients, dangers from hepatic amebic disease at times outweigh those that may result to the heart from emetine and treatment should be instituted. The added risk in the use of emetine under these circumstances, when its need is great, must be accepted. Adjustment of dosage schedules to fall within 1 mg per kilogram body weight daily for ten days was, in the eight patients cited, effective for the amebiasis and was accompanied by no demonstrable adverse effects on the already damaged cardiovascular system. The use of emetine in the presence of heart disease is discouraged except when necessary for forms of amebiasis endangering the patient's life and not effectively treated otherwise.

8 THE PRESIDENT'S ADDRESS

9 THE PATHOGENESIS OF ACUTE BACTERIAL LYMPHADENITIS

RALPH O. SMITH, M.D. (BY INVITATION), AND W. BARRY WOOD, JR., M.D.
St. Louis, Mo.

In an effort to clarify the role of lymphatic tissue in antibacterial defense, a study has been made of the cellular reactions in popliteal lymph nodes of rats inoculated in the foot pads with Type 1 pneumococcus.

Acute pneumococcal lymphadenitis is characterized by rapid infiltration of polymorphonuclear leucocytes into the intermediary sinuses of the node and prompt phagocytosis by both the macrophages of the sinuses and the recently arrived leucocytes. By seven hours the polymorphonuclear leucocytes are found densely congregated about the hilar region, and nine hours after inoculation the phagocytosed organisms have been digested and pneumococci are no longer seen in the node. At the end of twenty-four hours the node presents the picture of a subsiding inflammation with a marked macrophage reaction and regenerating follicles.

By eradication of hilar blood supply, direct intralymphatic injection of pneumococci, and analysis of cells in afferent lymph, it has been shown that the majority of polymorphonuclear leucocytes entering the intermediary sinuses come from capillaries lining these sinuses, whereas the leucocytes present in the subcapsular sinus come from the primary inflammatory focus in the footpad as well as from capillaries of the capsule and the subcapsular portions of the follicles.

Phagocytosis of pneumococci in the foot pad and popliteal node occurs in less than thirty minutes after inoculation. Because of the promptness with which the phagocytic reaction takes place, and because of the large surface area afforded the leucocytes by the nodal sinuses and interstitial tissues of the foot pad, it is assumed that the same nonantibody mechanism of "surface phagocytosis" is involved as that previously described in experimental pneumonia.

Fibrin formation in the sinuses of the node is rare. This finding may be related to the observation that five minutes after inoculation, mast cell granules, which are known to contain heparin, are strewn throughout the sinuses of the node. The mast cells become vacuolated and almost devoid of granules, later their granules appear to regenerate.

These studies indicate that, early in the course of acute infection, bacteria reaching a regional lymph node elicit a prompt leucocytic response in the node.

The resulting enhancement of filtration due to the congregation of leucocytes in the hilar sinuses and the immediate phagocytosis of bacteria in the absence of opsonin lead to rapid destruction of invading organisms. Thus an acutely inflamed lymph node, so frequently regarded as a passive filter, in reality plays an active role in antibacterial defense.

10 ANTIBODY FORMATION IN HUMAN SUBJECTS FOLLOWING THE INGESTION OF HEAT KILLED BRUCELLA ABORTUS

ABRAHAM I. BRAUDE, M.D., and DAVID GOLD, B.S., MINNEAPOLIS, MINN.

(INTRODUCED BY WESLEY W. SPINK, M.D.)

The agglutination test is used widely in the diagnosis of brucellosis. Caution must be exercised in its interpretation however because agglutinins are known to appear in the sera of persons without brucellosis. Eisele and McCullough have found that positive *Brucella* agglutination tests develop following cholera vaccination. This probably accounts for only a small percentage of false positive reactions. At the University Hospitals Aagaard has observed that *Brucella* agglutinins were present in 93 per cent of blood samples obtained from consecutive rural patients who were being studied in a dispensary service for various cases. The following investigation was undertaken to determine whether the repeated ingestion of nonviable *Brucella* organisms in milk would produce demonstrable agglutinins in the serum.

A preliminary study disclosed that no agglutinins appeared in the sera of guinea pigs following the oral administration of 100 billion heat killed *Brucella abortus* organisms in single or divided dosages. The same dose was then given in aqueous suspension to twenty three human volunteers in a single feeding and it was found that serum agglutinins had developed in four subjects. An attempt was made next to approximate the naturally occurring circumstances whereby *Brucella* enter the gastrointestinal tract in pasteurized milk. This was accomplished by the daily feeding to thirty six hospital patients of 100 million heat killed *Brucella* organisms in pasteurized milk obtained from *Brucella* free herds. After ten to twenty feedings during periods of two to four weeks significant titers of agglutinins were detected in eleven of the thirty six persons. When the total number of ingested *Brucella* was reduced to one million daily, it was found that one of eight additional patients showed a rise in titer. In a total of sixty nine individuals agglutinins were produced in sixteen following the ingestion of nonviable *Brucella* under these varying conditions. Titers ranged from 1:20 to 1:640.

The ability of dead *Brucella* to sensitize the skin to *Brucella* antigens was investigated in eighteen persons who ingested 100 million organisms daily for ten to twenty feedings. Sixteen of the eighteen had negative skin tests with *Brucellergen* antigen after the feedings were discontinued. Two persons with positive tests at the beginning of the experiment showed no alteration in skin sensitivity as a result of the feedings. The sera of thirteen subjects in whom agglutinins for *Brucella* had appeared were also tested for opsonins before and after the ingestion of *Brucella*. In seven of these there was an increase of ten to ninety over the initial opsonocytic index.

From these results it is concluded that the oral ingestion of nonviable *Brucella* may give rise to the production of agglutinins or opsonins but not to the acquisition of dermal hypersensitivity. This is offered as one explanation for the fairly high incidence of agglutinins in the blood of asymptomatic persons who inhabit areas where Bang's disease is prevalent in cattle. Under naturally

occurring conditions these dead organisms may be ingested in pasteurized milk or may result from the action of gastric juice on living organisms which enter the stomach in raw milk. Data have been accumulated demonstrating the marked anti-*Brucella* action of human gastric juice.

11 THE DEVELOPMENT OF STREPTOMYCIN-RESISTANT BACTERIA IN THE STOOLS OF PATIENTS TREATED FOR TUBERCULOSIS

MORTON HAMBURGER, M.D., JEROME R. BERMAN, M.D. (BY INVITATION),
AND ANGELINA FABRIZIO, M.S. (BY INVITATION), CINCINNATI, OHIO

The development of streptomycin-resistant pathogens during streptomycin therapy has been demonstrated often enough to establish this phenomenon as a serious therapeutic and public health risk. However, no studies have been made of the effect of streptomycin therapy on bacteria which normally lead a saprophytic existence in the body but which are nevertheless potentially pathogenic. To investigate this problem, studies have been made of the streptomycin resistance of coliform bacilli in the stools of patients given streptomycin for various types of tuberculosis.

Samples of stool were obtained when possible prior to therapy, and at various intervals during and after therapy. Saline suspensions of the stool were streaked on each of two plates: an eosin-methylene blue plate and a similar plate containing 100 μ g streptomycin per cubic centimeter. Growth was recorded after twenty-four, forty-eight, and seventy-two hours of incubation, photographs of the plates were made, and representative colonies were picked for more accurate determination of streptomycin resistance in a serial dilution test.

The study included seven patients with milary tuberculosis, eleven with nonmilary pulmonary tuberculosis, six with tuberculous peritonitis and three with tuberculous pericarditis. All received 1 or 2 Gm of streptomycin daily intramuscularly for one to twelve weeks, but no streptomycin by any other route.

Colon or aerogenes bacilli which grew freely in 156 to more than 2,500 μ g streptomycin per cubic centimeter of medium appeared during treatment in the stools of six out of seven patients with milary tuberculosis and in four of six patients with tuberculous peritonitis, but in no case of pericarditis and in only one of eleven cases of nonmilary pulmonary tuberculosis. Sensitive strains from these patients were inhibited by 0.6 to 2.4 μ g per cubic centimeter.

The ecologic relationship in the stool between sensitive and resistant variants was interesting. Though sometimes the resistant forms entirely replaced the sensitive strains during treatment, sensitive bacilli returned after cessation of therapy and usually ultimately completely replaced the resistant forms. This phenomenon was not a reversion of resistant to sensitive variants, nor a manifestation of "streptomycin-dependency," because resistant strains retained their resistance after more than 100 passages in streptomycin free broth and after twelve passages through untreated mice.

In two patients with tuberculous peritonitis, resistant bacilli decreased in number or disappeared during the stage of clinical improvement while the patients were still receiving streptomycin.

12 BACTEREMIA FOLLOWING TOOTH EXTRACTION PREVENTION WITH PENICILLIN AND 3,4-DIMETHYL 5-SULFANILAMIDE ISOXAZOLE (GANTROSAN)

PAUL S. RHODES, M.D., and WARREN R. SCHRAM, D.D.S. (By Invitation)
CHICAGO, ILL.

WITH THE TECHNICAL ASSISTANCE OF DORIS ADAIR

The present study was undertaken with the following objectives: (1) To confirm the contention of other investigators that a temporary bacteremia can be demonstrated in a fairly high percentage of persons immediately after tooth extractions; (2) To learn if possible which teeth are most likely to cause bacteremia when extracted or traumatized; (3) To determine the effectiveness of penicillin and a new sulfonamide, 3,4-dimethyl 5-sulfanilamide isoxazole (Gantrosan), in preventing the blood stream dissemination of bacteria.

One hundred twenty-two blood cultures were done immediately after teeth were extracted either because the teeth were infected or to prepare the gums for full dentures. In a group of twenty-eight patients received intra-muscular procaine penicillin in oil (300,000 units) two hours before extraction and the blood culture was positive in two (7.2 per cent). In a group of eight patients receiving 100,000 units of penicillin in aqueous solution two hours before tooth extraction there were no positive blood cultures. Eighteen blood cultures were from patients who received 2 Gm. of Gantrosan orally two hours before tooth extraction and none of these were positive. Thus in the entire protected group the incidence of temporary bacteremia was 3.7 per cent. In the control group of sixty-eight in which the patients received no preoperative medication 35.3 per cent of the blood cultures were positive for nonhemolytic streptococci.

Quantitative cultures were made of the snapped off roots of the teeth extracted. The bacterial counts of the teeth removed in the protected and non-protected groups were approximately the same. In attempting to correlate the roentgen appearance of the teeth with bacterial counts of the root ends and incidence of postoperative positive blood cultures, no constant relationship could be determined. Frankly abscessed teeth were associated with post-extraction bacteremia a little more often than roentgenographically negative teeth, but in many instances bacteremia resulted from extraction of the latter also.

The extreme importance of protecting persons with known valvular heart disease with penicillin or sulfonamide before tooth extractions is obvious. To be on the safe side the procedure should probably precede all tooth extractions.

PROGRAM

SCIENTIFIC PROGRAM—OCTOBER 29, 1948

FRIDAY AFTERNOON, 2 00 P M

13 RELATIONS BETWEEN VOLUMES OF CLOSED HYPOTHERMAL CEREBRAL LESIONS AND SYMPTOMS IN RABBITS

C BRUCE TAYLOR, M D (BY INVITATION), GEORGE M HASS, M D, AND
JOHN E MALONEY, M D (BY INVITATION), CHICAGO, ILL

Acute closed cerebral lesions characterized by hemorrhage, necrosis, and progressive edema were produced hypothermally in rabbits without interrupting the continuity of the calvarium or introducing variables incidental to mechanical trauma. The dimensions and locations of lesions in the cerebrum were controlled so that they could be reproduced topographically and quantitatively in successive animals. Although hemorrhage, edema, and necrosis varied slightly in lesions which were otherwise identical, the variations were restricted to discrete volumes of injury.

When unilateral or bilateral lesions of the cerebrum occupied less than 9.4 volumes per cent of the brain, symptoms were negligible. When the lesions occupied 9.4 to 18.5 volumes per cent of the brain, severe symptoms developed in many animals. The data indicated that the minimum lethal volume of cerebral damage in 50 per cent of more than one hundred animals was 14.3 per cent of the volume of the brain. Severe clinical courses with an average postoperative duration of about seven hours and fatal termination always occurred when the lesions occupied more than 18.5 volumes per cent of the brain. A great majority of the animals that died had a normal postoperative period of behavior. Secondary lapse into stupor was a dependable indication of impending coma and eventual death within twenty-four hours after the time of completion of the operation.

These data indicate that a quantitative experimental approach to the problem of treatment of acute expanding closed intracerebral lesions characterized by local necrosis, hemorrhage, and edema can now be made. The postoperative duration of life can be predicted from the magnitude of the lesions which are produced and this duration is sufficient to permit evaluation of most therapeutic methods now used empirically in the treatment of acute expanding closed intracerebral lesions in human beings.

14 PARA-AMINOBENZOIC ACID THERAPY IN SCLERODERMA AND LYMPHOBLASTOMA CUTIS

CHRIS J D ZARAFONETIS, M D, ANN ARBOR, MICH

(INTRODUCED BY FRANK H BETHELL, M D)

Previous reports have dealt with the effects of para aminobenzoic acid (PABA) in leukemia, lupus erythematosus, dermatomyositis, and dermatitis herpetiformis. The purpose of this communication is to describe the results of PABA therapy in patients with scleroderma and with lymphoblastoma cutis.

The patients used in this study were made available by Dr. A. C. Curtis, Professor of Dermatology at the University of Michigan Medical School.

Five patients, presenting a wide range of sclerodermatous involvement, were treated with sodium (NaPAB) and/or potassium (KPAB) para-aminobenzoate. Improvement occurred in four and was most evident in the more extensively involved patients. The sclerodermatous areas gradually softened and became thinner with consequent increase in range of motion of the affected part. The fifth patient developed drug fever and therapy was discontinued.

Similarly, five patients with lymphoblastoma cutis were treated with NaPAB. All experienced relief from pruritus and objective improvement of the skin. This was characterized by diminution in erythema and infiltration. Treatment with NaPAB was discontinued in all five because of the development of edema. One of these patients was changed to KPAB therapy with loss of edema and striking improvement. Treatment was maintained for nine months in this subject. Of incidental interest has been the concomitant darkening during therapy of the patient's previously gray hair.

Administration of large amounts of PABA compounds results in glycosuria. This may not be verified in fermentation tests since the concentration of PABA in the urine of these patients will inhibit yeast fermentation activity.

All other forms of therapy for their respective disorders had been attempted in these patients before PABA therapy was undertaken. It would seem therefore, that PABA has a practical though limited value in the treatment of scleroderma and lymphoblastoma cutis. More important perhaps is the possibility that further study of PABA may yield information as to the mechanisms involved in these and related conditions of unknown etiology.

15 THE INHIBITORY EFFECT OF NITROGEN MUSTARD (BIS BETA CHLOROETHYL AMINE) ON THE DEVELOPMENT OF HUMORAL ANTIBODIES, CUTANEOUS HYPERSENSITIVENESS AND VASCULAR LESIONS IN RABBITS FOLLOWING INJECTIONS OF HORSE SERUM

SAMUEL C. BURKANTZ, M.D. (BY INVITATION), GUSTAVE J. DAMMIN, M.D.,
KERR S. WILSON, M.D. (BY INVITATION), AND MARY C. JOHNSON, A.B.
(BY INVITATION), ST. LOUIS, MO.

The vascular lesions that appear in the rabbit following the injections of horse serum are similar to those observed in certain diffuse vascular diseases in man. The latter are believed by some to result from hypersensitiveness. Because of these similarities the pathogenesis of the experimental lesions has been intensively investigated. The relationship of humoral antibody and cutaneous hypersensitiveness to the vascular lesions is still to be defined. Conflicting reports have been published concerning the influence upon the vascular lesions of various agents believed to affect antibody formation, antigen-antibody combination, or the cellular effects of the latter.

Antihistamines were used in our initial attempt to modify the vascular lesions. Neither Benadryl nor Neohetramine was observed to affect the lesions, the development of antibodies, or cutaneous hypersensitiveness.

Because of the ability of sulfur and nitrogen mustards to suppress antibody formation (Hektoen and Corpe, Phillips and co-workers and Spurr), we investigated the effect of bis beta chloroethyl amine (HN) on the formation of antibody as well as on the development of cutaneous hypersensitiveness and vascular lesions.

A group of rabbits weighing 20 to 25 kilograms were given, at four day intervals, a total of seven intravenous injections of 0.5 mg HN_2 per kilogram. Two days after the third injection, each received 10 cc of horse serum per kilogram intravenously. A second group of rabbits received an identical dose of horse serum at the same time, but was not treated with HN_2 . Two days after the seventh mustard injection and fourteen days after the serum injection, all animals were skin-tested with varying amounts of horse serum after which they were sacrificed. Blood serum samples obtained one week after injection of horse serum and again at the time of sacrifice were studied for the presence of horse serum antigen and antibody by precipitin tests. Pooled terminal serums of the two groups were separately analyzed quantitatively for total antibody nitrogen.

A marked leucopenia and moderate bleeding tendency developed in the HN_2 treated animals but they otherwise appeared healthy and gained weight. Antigen persisted the same length of time in the untreated as in the treated rabbits. Antibody appeared after one week in the control animals but not until the end of the second week in the mustard-treated group. In the pooled terminal serums of the control group 0.062 mg antibody nitrogen per milliliter was present and but 0.031 mg in the treated. There was moderate suppression of skin hypersensitiveness in the HN_2 treated group. Eighty per cent of the control group developed arterial and endocardial lesions whereas there were no vascular lesions observed in the treated animals.

While the data suggest that humoral antibody is important in the pathogenesis of the experimental vascular lesions, this has not yet been completely established, in view of the known effect of HN_2 upon protein structures and enzyme systems other than those involved in antibody formation. In this regard we have found that HN_2 in vitro had no effect upon the precipitation of rabbit antihorse serum by horse serum.

Summary—The nitrogen mustard, bis beta chloroethyl amine, was observed to suppress the development of humoral antibodies, cutaneous hypersensitiveness, and the vascular lesions in rabbits induced by horse serum.

16 EFFECT OF RUTIN UPON THE RESORPTIVE TOXICITY OF CERTAIN DRUGS

R. K. RICHARDS, M.D., NORTH CHICAGO, ILL.

Attempts to demonstrate an effect of rutin upon the capillaries by experimental methods have met with but limited success. Recently, reduction of trypan blue diffusion after local irritation of the skin of rabbits has been described (Ambrose and DeEds, *J. Pharm.* 90: 359, 1947), and also the prevention of irradiation injury in rats (Griffith and co-workers, *Proc. Soc. Exptl. Biol. & Med.* 64: 332, 1947).

These procedures do not lend themselves readily to a quantitative measure of rutin action.

A new approach to this problem is based upon our early observation that sodium bisulfite in small concentrations (0.1 to 0.4 per cent) greatly increased toxicity of epinephrine or procaine if added to the drugs and injected intramuscularly or subcutaneously, but not intravenously. This "bisulfite phenomenon" was shown to be due to a local effect upon the capillaries by the bisulfite ion causing a faster absorption rate. Only drugs having a wide margin between the intravenous and the subcutaneous or intramuscular toxicity show a positive bisulfite phenomenon.

If rutin is injected intravenously in rats prior to the administration of the toxic drugs to which sodium bisulfite has been added the increased toxicity of epinephrine is greatly reduced without affecting the toxicity of epinephrine as such. This procedure permits a quantitative estimation of rutin action upon the capillaries.

A similar effect could be demonstrated against the increased toxicity of procaine caused by sodium bisulfite. However in contrast to the observations with epinephrine rutin also decreased toxicity of plain procaine solutions. It was shown that high concentrations of procaine exert a dilating effect upon capillaries which is antagonized by rutin.

Definite reduction of toxicity by previous rutin administration could also be shown with strychnine but little if any with Metrazol. The former of these two drugs has a much greater margin between the intravenous and the intramuscular toxicity than the latter thus the prolongation of the absorption produced by rutin permits the detoxification of the drug to become partially effective. The described procedures permit the use of bisulfite phenomenon and the decrease of the absorptive toxicity of certain drugs as a tool for further research on rutin on other drugs with specific effects upon the capillaries.

EFFECT OF SEDATIVES ON URINARY VOLUME OF PREGNANT WOMEN

WILLIS L. BROWN, M.D., J. T. BRADBURY, S.C.D. and OTTO F. KRAUSHAAR, M.D.
IOWA CITY, IOWA

(INTRODUCED BY W. M. FOWLER, M.D.)

One of the cardinal findings in toxemia of pregnancy is edema. In a previous communication before this Society we reported the effectiveness of various diuretic agents in the mobilization and excretion of sodium and water. This paper reports our observations on the antidiuretic effect of morphine and other sedative drugs in pregnant women.

A series of patients was given a constant intravenous infusion for five hours and hourly urine specimens were obtained for eight hours. On test days these patients were given injections of a sedative and the effect on the urinary output and chloride excretion was measured. Morphine reduced the urinary output by 50 per cent without any significant alteration in total urinary chlorides. The fluid retention was further manifested by a transitory increase in body weight.

Another series of patients was given oral fluids as a liquid breakfast of 1,000 c.c. during the hour of 7:00 to 8:00 a.m. The urine volumes were then measured at hourly intervals for four hours. On test days the sedative was administered one hour after the liquid breakfast. Morphine, Demerol, codeine and Amytal caused similar depression in urinary volume. Paraldehyde and Verin have not been found to have an antidiuretic effect.

DeBodo reported that morphine caused a release of the antidiuretic hormone from the pituitary in dogs. Studies were undertaken to determine the mechanism of this antidiuresis in women. The similarity of response by normal subjects and patients with diabetes insipidus to morphine suggests that this antidiuretic effect is not mediated through the posterior pituitary. Since hypnosis sleep did not induce this response it is apparent that the antidiuresis was effected by some mechanism other than sleep itself.

These observations suggest that morphine and similar drugs should be used with caution in edematous states. Tables and graphs will present these data.

18 EVALUATION OF NEUROGENIC AND HUMORAL FACTORS IN BLOOD PRESSURE MAINTENANCE IN NORMAL AND TOXEMIC PREGNANCY USING TETRA- ETHYLAMMONIUM CHLORIDE

ALBERT A. BRUST, M.D. (BY INVITATION), N. S. ASSALI, M.D.
(BY INVITATION), AND EUGENE B. FERRIS, M.D.
CINCINNATI, OHIO

Transient elimination of neurogenic tone by the action of sympathetic blocking agents has afforded a new physiologic approach to evaluation of mechanisms operative in sustaining blood pressure at normal or hypertensive levels. Tetraethylammonium chloride (TEAC), administered intravenously in 400 mg doses, induces a temporary blockade of impulse transmission at the autonomic ganglia. When neurogenic tone has been abolished in this manner, the arterioles remain responsive to humoral agents, and thus the remaining blood pressure (TEAC floor) must be maintained by humoral mechanisms together with intrinsic vascular tone.

Toxemia of pregnancy with its attendant hypertension has long been regarded as a humoral disorder despite the lack of physiologic evidence. In an effort to evaluate the relative importance of humoral and neurogenic factors in the blood pressure of patients with toxemia as well as those with normal pregnancy, we have utilized TEAC assay to study ten normal nonpregnant women, ten normal term pregnancies, eighteen cases of preeclampsia, and five cases of eclampsia.

In each of the normal term pregnancies, the prepartum response to autonomic block was a marked fall in blood pressure to mean levels of 55 to 65 mm Hg. Within twenty-four to forty-eight hours post partum, all these patients showed a striking rise in TEAC floors, the responses corresponding exactly to those of the normal nonpregnant controls.

Strikingly different responses occurred in the patients with toxemia. Prepartum TEAC floors invariably remained elevated above those of nonpregnant controls and were consistently 25 to 70 mm Hg higher than those of the normal pregnancies. With subsidence of toxemia post partum, floors promptly fell to the normal nonpregnant range. The diastolic TEAC floor appears to be of the greatest significance in these studies, for it never fell below 80 mm Hg in toxemia yet was never higher than 56 mm Hg in normal pregnancy. The highest diastolic floors consistently occurred in those patients who clinically were most toxic, regardless of the height of the pretest blood pressure.

The results suggest that (1) The hypertension of toxemia of pregnancy is supported primarily by an excessive degree of humoral tone. (2) Conversely, the blood pressure in normal term pregnancy is maintained largely by neurogenic and intrinsic tone. (3) Within forty-eight hours post partum of normal pregnancy there is a return to nonpregnant control mechanisms (humoral predominating). (4) Clinical assay with TEAC may be a helpful aid in diagnosis of toxemia of pregnancy and in the evaluation of changes in severity during its course.

19 THE EFFECT OF WATER BY VEIN ON THE MORE SEVERE COMPLICATIONS OF CARDIOVASCULAR RENAL DISEASE

F R SCHEM, M D, AND J A LAYNE M D, GREAT FALLS MONT

Our most seriously ill patients showed the greatest need for plain water and were the least able to take or retain adequate amounts by mouth. With a proper regulation of sodium intake, including a minimal use of plasma, blood and other sodium laden solutions which yield no free water they were given plain water by vein in amounts designed to restore and maintain water balance.

The solutions used in about 500 periods of observation contained 50 or 25 Gm of dextrose (quickly oxidized or stored) in 1000 cc of distilled water which is quickly dispersed throughout the 50 liters of total body water. The usual volume given was 1,000 cc, with a range of from 500 to 2,000 cc at one time. The total amounts given in one day ranged from a 500 cc supplement to from 3,000 to 6,000 cc daily when the oral intake was nil or negligible. The rate of flow was from 10 to 20 cc per minute. (It would have required too many hours to administer the larger totals at slower rates and it was noted that reactions occurred more frequently with the fatigue and annoyance of long drawn out venoclyses.) The effect of the larger amounts of fluid by vein was observed over periods of from five to thirty five consecutive days.

There was no detectable clinical or laboratory evidence of harmful dilution observed immediately after a venoclysis or after several days of large amounts of these isotonic or hypotonic dextrose solutions. At the moment of completion of a venoclysis the changes in venous pressure were found to range from a drop of a few centimeters, through no change to a rise of as much as 13 cm. no objective or subjective evidence of left ventricular failure or pulmonary edema were noted with the rises in venous pressure. The venoclyses did not precipitate pulmonary edema in some cases which had recently experienced an acute profuse attack, and retinal edema and choked discs were seen to improve and convulsions came under control during some periods of observations.

In severe myocardial infarction with shock the water by vein was used effectively to prevent the development of anuria and azotemia, or for their correction. Severe congestive failure that had resisted sodium restriction and acid and mercurial diuretics was observed to respond to the increase in water intake made possible by intravenous supplements.

In many instances, what appeared to be an anuria with uremia due to so called renal shut down proved to be an anuria due to an inadequate intake of plain water. For water became available to the kidneys and they elaborated urine readily again, only after a large existing plain water deficit of from 4,000 to 7,000 cc and a high daily vaporization loss of 2,000 to 4,000 cc were provided for. In these patients the large amounts of plain water given sometimes entirely by vein did not induce heart failure and relieved the anuria and uremia without resort to decapsulation of peritoneal lavage.

20 THE NATURE OF THE ALTERED RENAL FUNCTION IN LOWER NEPHRON NEPHROSIS

DANIEL MARSHALL, M D (BY INVITATION), AND WILLIAM S HOFFMAN, M D
CHICAGO, ILL

Serial determinations of clearances of mannitol, *p* aminohippurate, urea, and creatinine, and of tubular excretory mass were carried out in three subjects in the phase of diuresis and recovery from lower nephron nephrosis. In addition, urine-plasma ratios of nonprotein nitrogen were followed in these and three other patients with lower nephron nephrosis during the whole course of illness. With these data it was possible to extrapolate back to the period of oliguria and recognize the general nature of the functional alteration.

In two subjects the first function tests gave negative values for tubular excretory mass and impossibly high values for filtration fraction and ratio of *p*-aminohippurate clearance to tubular excretory mass. In subsequent tests these distortions disappeared, but the absolute values for clearances remained lower than normal. Complete restitution of renal function to normal did not occur until three to seven months had elapsed.

At the beginning of diuresis, the concentration ratio of nonprotein nitrogen remained as low as during the oliguric period. After several days of diuresis, the concentration ratio began to rise steadily even as the urine volume increased, indicating improvement in tubular function.

These data are consonant with the idea that the functional renal lesion in lower nephron nephrosis is a diminished renal blood flow in association with a loss of specific function of the lower nephron. Consequently, the limited amount of modified glomerular filtrate reaching the lower nephron is almost completely reabsorbed. A gradient diffusion through the damaged cells appears to be present which allows a greater reabsorption of *p*-aminohippurate than of mannitol and which is thus responsible for the distorted renal clearance tests. Recovery seems to be produced first by an increase in effective renal blood flow, followed later by a repair of tubular function. The gradient diffusion is apparently the first tubular defect to disappear. The total recovery of normal specific tubular function is much slower.

21 DANGERS FROM THE USE OF THE RICE DIET

LEO F NARUT, M D (BY INVITATION), AND GEORGE C TURNBULL, M D
EVANSTON, ILL

The present public interest in the Kempner rice diet led us to make a critical evaluation of this diet as an adjunct to the treatment of hypertensive heart disease. The results of this and more liberal diets have been recorded in the treatment of fifty-seven patients with hypertensive cardiovascular disease on the medical services of the Cook County Hospital and the Evanston Hospital. Supportive case reports point out that a simple convenient criterion of the urine specific gravity tends to indicate that one group of patients is benefited by the rice diet, another is unaffected, while still a third is made worse. The organism as a whole must be considered, not can one overlook the fact that fundamental physiologic and biochemical principles govern the potential efficacy of this type of diet. One must be mindful of the physiology of extra and intracellular fluid, renal physiology, circulatory dynamics, and pulmonary ventilation of the role of blood, psychosomatics, and the endocrine system, and of the influence of medication. Blood protein and sodium levels must be given due considera-

tion. Illustrative groups of patients having hypertensive heart disease are presented, showing the influence of the renal reserve as reflected in the urine specific gravity and the influence of a variable external environment. Twenty five patients with a good renal reserve indicated by a urine specific gravity of 1.020 or better were benefited by the rice diet especially where cardiac decompensation was present. The improvement noted is attributable to the results of weight reduction by dietary restriction. Twenty four patients with a specific gravity range of 1.012 to 1.020 were possibly benefited by salt and protein restriction but again to a limited extent depending upon the status of the extra renal environment. Light patients with a specific gravity fixed at 1.010 were benefited at first but subsequently became worse when dietary restriction was continued. Serum sodium and chloride levels are altered, pre-renal azotemia with sequelae supervenes on a kidney with poor reserve and clinically the manifestations of weakness, lethargy, abdominal cramps, oliguria and disturbances in acid base balance become apparent. We consider urine specific gravity fixed at 1.010 as a warning signal to proceed with caution in the use of the rice diet and we believe it imperative to keep in mind the various possibilities which may be encountered especially in patients who have poor reserve in organs other than the kidney. When blood sodium levels begin to fall the rice diet should be discontinued. The narrow border between the pre-uremic state and uremia necessitates the addition of salt and blood or fluids to the therapeutic regime in order to reverse the process and thereby possibly avoid a casualty.

22 THE EFFECTS OF BACTERIAL PYROGENS ON MALIGNANT HYPERTENSIVE PERSONS

ROBERT D. TAYLOR, M.D., A. C. CONCORAN, M.D., H. H. LERTIG, M.D.
(BY INVITATION), AND IRVING H. PAGE, M.D. CLEVELAND, OHIO

Thirty five patients exhibiting the syndrome of malignant hypertension were treated with repeated injections of bacterial products which elicited leucocytosis and fever. The effects were evaluated from the levels of arterial pressure, cardiac, cerebral and renal functions and funduscopic changes. The responses to all the materials were so similar that they can be considered together.

The diastolic blood pressure of sixteen of the thirty five patients was reduced by treatment from 126 mm. Hg. mean (range 110 to 150) to average 100 mm. Hg. during five to nineteen weeks. Papilledema disappeared in all but two, one of whom still is receiving treatment. The persistent elevation of the optic disc in the other may represent a lesion of the nerve. Fourteen patients became free of retinal hemorrhages. One of the remaining two is still under treatment and, in the other, the severity grading was reduced from 4 to 1. Most of the fresh exudates disappeared however in nine persons scars of previous disease persisted.

Before treatment, five of these sixteen patients presented signs of congestive heart failure, all evidences of which were relieved during therapy. Electrocardiograms showing signs of damage became normal in seven and improved in the other nine. Heart size (teleroentgenogram) diminished from plus 18 per cent before to plus 5 per cent after treatment.

Renal function at first was moderately depressed in nine patients but was eventually restored to or above control levels.

Except for persistent elevation of arterial pressure remissions have lasted for an average of twenty four months and up to thirty months.

Eleven of the sixteen patients who responded well are living after fourteen to thirty one months. Three of the remaining five discontinued treatment after

three to thirteen weeks and died within three months of cerebral hemorrhage. Another died of apoplexy ten months after treatment with pyrogen and six months after sympathectomy. The fifth, the only one with return of the malignant phase, died of cerebral hemorrhage six months after treatment was begun.

Of the remaining nineteen patients, eleven responded more briefly and in less degree than the sixteen described, while eight showed no change. All but two are dead. These two are at present under treatment.

Tolerance to pyrogens appeared in five to nineteen weeks, after which arterial pressure rose, but usually without reappearance of the malignant syndrome.

The outcome was not predictable from arterial pressure, the retinopathy, or the extent of cardiac disease. Six patients who were virtually blind and four who had congestive failure responded favorably. The significance of renal function is shown by the fact that TmPAH averaged 62 mg per 1.73 sq M in the sixteen who responded well (range 48 to 109), the mean was 26 (range, 12 to 40) in those responding poorly, and 20.8 (range, 7 to 32) in those with no response.

In summary, the malignant phase of essential hypertension can be remitted in some patients by repeated injections of bacterial pyrogens provided renal damage has not advanced to the extent that TmPAH is less than 45 per milligram per minute per 1.73 sq M of body surface.

23 A TEST FOR THE PRESENCE OF THE HYPERTENSIVE Diencephalic Syndrome Using Histamine

HENRY A. SCHROEDER, M.D., AND MELVIN L. GOLDMAN, M.D. (By Invitation)
St. Louis, Mo

A syndrome associated with arterial hypertension has been described by Page which he called the hypertensive diencephalic syndrome. Occurring usually in women, but also in men, it is characterized by labile hypertension and attacks of a periodic appearance of a blotchy rashlike blush on the face, chest and shoulders, associated often with headache, lacrimation, and signs of vasoconstriction in the extremities. Attacks of this disorder probably represent some neurogenic disturbance associated with hypertension. In susceptible individuals this syndrome has been reproduced by the intradermal injection of 0.25 mg of histamine, reaching its height five to ten minutes after the injection. Of fifty patients with normal blood pressure, the syndrome was made to appear in five. Of thirty-three with neurogenic hypertension it appeared in twenty-six. In fourteen patients with other types of arterial hypertension it appeared in none. Four subjects in whom the reaction to histamine was marked failed to react after lumbar sympathectomy. When the reaction occurred, the symptoms of which the patient complained usually were reproduced, including the typical hypertensive headache. Antihistaminic agents only partially blocked the reaction in one subject. It was not reproduced by the administration of epinephrine or Mecholyl. The possible role of histamine like substances in causing some of the symptoms of neurogenic hypertension is suggested.

PROGRAM

SCIENTIFIC PROGRAM—OCTOBER 30 1948

SATURDAY MORNING, 9 15 A M

24. GLYCOSURIA SIMULATED BY THE ADMINISTRATION OF ASCORBIC ACID ITS OCCURRENCE AND DIFFERENTIATION

JOHN C MITCHELL, M D (BY INVITATION), AND CARL I WILTER M D
CINCINNATI, OHIO

The confusion afforded by repeatedly positive Benedict tests on urine of a diabetic patient whose diabetes was thought to be well controlled and who was receiving large doses of ascorbic acid prompted us to investigate the reducing power of this substance in the urine as measured by Benedict's qualitative test and the Clinutest tablet.

Quantitative *in vitro* experiments were performed in order to determine the amount of ascorbic acid which must be present in solution to give a positive Benedict test and Clinutest. It was found that 0.2 mg of ascorbic acid was sufficient to reduce 5 ml of Benedict solution to a 1 plus reaction and the Clinutest to a 'trace'. 1.9 mg of ascorbic acid produced a 2 plus with both tests. 2.1 mg a 3 plus while 8.0 mg were required to give a 4 plus reaction. It was found that when compared by weight ascorbic acid was a more powerful reducing substance than glucose when tested by these methods. It was further shown that ascorbic acid and glucose when present together in solution have an additive effect in this reduction reaction.

In vivo experiments showed that when ascorbic acid was administered in large doses parenterally (now a common surgical practice) or by mouth there was usually sufficiently rapid urinary excretion of this substance to give a positive Benedict test or Clinutest. Following the intravenous administration of 500 mg of ascorbic acid the majority of the patients gave a 1 plus Benedict test in two hours and had a urinary output ranging between 38 and 136 mg per cent ascorbic acid. Following the intravenous administration of 1,000 mg of ascorbic acid, all but one of the patients had a 2 plus Benedict test after two hours. The urinary concentration of ascorbic acid ranged from 430 to 980 mg per cent at that time.

A simple method depending on oxidation of ascorbic acid in alkaline medium has been devised for differentiating this substance from glucose in the urine. Two milliliters of urine are made alkaline with sodium carbonate followed by the addition of 6 to 8 drops of hydrogen peroxide. This procedure rapidly destroys the reducing power of ascorbic acid but does not interfere with the reducing power of glucose as measured by Benedict's test and the Clinutest. This procedure is useful not only in the differentiation between glycosuria and a false positive Benedict test due to ascorbic acid in routine urinalyses but also enables one to follow more accurately the glycosuria of a diabetic patient who is receiving large doses of ascorbic acid.

25 "STEROID DIABETES" ASSOCIATED WITH CUSHING'S SYNDROME AND EXCRETION OF 17-HYDROXYCORTICOSTERONE (COMPOUND F) IN URINE, METABOLIC STUDIES

R G SPRAGUE, M D, ALVIN B HAYLES, M D (BY INVITATION), H L MASON, PH D, M H POWER, PH D, AND W A BENNETT, M D (BY INVITATION)
ROCHESTER, MINN

The diabetes which is commonly associated with Cushing's syndrome is probably explainable on the basis of an overproduction of carbohydrate active steroid hormones by hyperplastic or neoplastic adrenal cortices. Such diabetes should, therefore, resemble the "steroid diabetes" produced by Ingle and co-workers in rats by the administration of 17-hydroxy-11 dehydrocorticosterone (Compound E) or 17-hydroxycorticosterone (Compound F), that is, it should differ from ordinary diabetes, particularly of the juvenile type, in being more resistant to insulin and in being mild during fasting. Furthermore, since one of the effects of the carbohydrate-active steroids is to stimulate the production of sugar from protein precursors, this type of diabetes should be characterized by the excretion of relatively large amounts of nitrogen in the urine, even when glycosuria is minimized by the use of diet or insulin, or both.

Observations which lend support to the foregoing ideas were made in the case of a 14-year-old boy with severe diabetes associated with Cushing's syndrome due to hyperplastic adrenal cortices. In addition to diabetes, the patient presented most of the classic features of Cushing's syndrome, including hypertension, osteoporosis, muscular weakness, and a hypochloremic, hypokalemic alkalosis of marked degree. That the diabetes was due to an overproduction of carbohydrate-active adrenal steroids was suggested by the fact that the urinary excretion of "cortinlike substances" ("11-oxysteroids") was remarkably high (about 17 mg daily, or about 200 times normal). Indeed, 17 hydroxycorticosterone was isolated from the urine, 191 mg of purified hormone being obtained from a twenty-five day collection of urine.*

Metabolic studies revealed that the diabetes exhibited the features of "steroid diabetes" in animals. It was of more than usual severity (in terms of insulin requirement), glycosuria being incompletely controlled with 130 units of insulin given daily while the patient received 187 Gm of carbohydrate daily in the diet. Unlike the usual behavior in ordinary juvenile diabetes, however, the urine became virtually free of sugar (24 Gm in twenty-four hours) and ketonuria was absent when food and insulin were withheld for twenty-four hours. (This amelioration of glycosuria with fasting and withholding of insulin was in marked contrast to the behavior of patients having both Addison's disease and diabetes who were previously studied by us, in whom withdrawal of insulin and fasting during the administration of Compound E resulted in the rapid development of severe diabetic acidosis.) As in the case of steroid diabetes in animals, nitrogen balance was decidedly negative with an intake of 57 Gm protein daily. Likewise, as suggested by the presence of osteoporosis, the balances for calcium and phosphorus were also negative.

The patient died after surgical resection of one hyperplastic adrenal gland. At necropsy pronounced hypertrophy and hyperplasia of the adrenal cortices, a small thymoma, a parathyroid adenoma (not hyperfunctioning), osteoporosis and bilateral renal calculi were found.

The clinical behavior of the diabetes, the metabolic data, and the finding of large amounts of 17-hydroxycorticosterone (Compound F) in the urine seem

*Mason H L and Sprague R G Isolation of 17-hydroxycorticosterone From the Urine in a Case of Cushing's Syndrome Associated With Severe Diabetes Mellitus J Biol Chem 175 451-456 1948

to justify the conclusion that the patient had 'steroid diabetes' analogous to that produced in animals by the administration of carbohydrate active adrenal steroids

26 ROLE OF THE ADRENAL CORTEX IN URATE METABOLISM AND IN GOUT

WILLIAM D. ROBINSON, M.D. JEROME W. CONN, M.D. WALTER D. BLOCK, Ph.D.
(By Invitation) and LAWRENCE H. LOUIS, Sc.D. (By Invitation)
ANN ARBOR, MICH.

Urate metabolism on a constant diet has been studied in three normal and one gouty subject during administration of approximately 50 mg. (Armour's Standard) of purified pituitary adrenocorticotrophic hormone intramuscularly daily, in divided doses for five to ten consecutive days. By using a specific enzymatic method employing uricase to determine blood and urine urates errors, inherent in the conventional colorimetric methods were avoided.

Following the administration of adrenocorticotrophic hormone to normal subjects, the urate excretion increased from 50 to over 100 per cent above base line values. This increase appeared during the first twenty-four hours and was well sustained reaching its peak on the sixth, seventh and ninth injection days respectively, in the three subjects. It was accompanied by an increase in excretion of nonurate chromogen in all three but this was irregular and not sustained during the injection period. There was an apparent decrease in blood urate when determined by direct colorimetric methods which are known to be influenced by other reducing substances but no significant change in the blood content of urate or of nonurate chromogen as measured by the uricase method. On the first postinjection day there was a sharp drop in urinary urate excretion to near basal levels, followed by a definite increase on the second to fifth post injection days. There was associated other evidences of a rebound in pituitary adrenal cortical activity at this time.

The injection of desoxycorticosterone acetate in doses of 20 mg. daily to a normal subject for ten days did not produce any significant effect on urine or blood urate levels.

The chief differences in response of the gouty patient to adrenocorticotrophic hormone as contrasted to normal subjects were (1) absence of a significant increase in excretion of nonurate chromogen (2) a sharp decrease in true blood urate to less than one half of the base line level so that loss from body fluids by simple increased renal excretion could account for one half to three fourths of urinary increase as compared to normal subjects where only negligible quantities could be accounted for on this basis and (3) absence of any secondary increase in urate excretion during the postinjection period. Effects on blood sugar, glucose tolerance, glycosuria, urinary nitrogen, amino acid and 17-ketosteroid excretion were similar to those seen in the normal subjects, except for the absence of any evidence of a rebound in hormonal activity during the postinjection period.

The gouty subject who had been free of attacks for nine months preceding study had a mild but definite attack on the third to fifth postinjection days at a time when all data suggested a depression of adrenal cortical activity. Talbott and associates (1935-1940) described cyclic changes in urate, electrolyte, and water excretion in patients with gout and related these changes to acute gouty attacks. Their data can be interpreted as reflecting cyclic changes in adrenal cortical activity with attacks occurring during periods of decreased

function. A common denominator for many of the incidents which have long been recognized as capable of provoking acute attacks of gout is furnished by their ability to affect pituitary-adrenocortical activity.

27 INFLUENCE OF PHYSICAL FITNESS AND CONVALESCENCE FROM MAJOR SURGICAL PROCEDURES ON THE MAGNITUDE OF THE RESPONSES TO EXERCISE OF THE BLOOD AND URINE LACTATE

DAVID I. ABRAMSON, M.D., WARREN H. COLE, M.D., ROBERT W. KEETON, M.D.,
MAURICE GEPHARDT, M.D. (BY INVITATION), JOSEPHINE M. DYNIEWICZ,
PH.D. (BY INVITATION), SOPHIE J. PRESLEY, M.D. (BY INVITATION),
AND GEORGE LAVERS, M.D. (BY INVITATION)
CHICAGO, ILL.

The changes in the values of the blood and urine lactate produced by exercise on a treadmill were studied in a group of fifty patients, in various states of physical fitness, before and after hemorrhaphy or cholecystectomy.

Precoperatively, with the same exercise load (three minutes on the treadmill), the maximal lactic acid level attained in the blood and the total quantity in the postexercise urine specimen were found to be much greater in patients in poor physical condition than in those in excellent shape. Generally, similar differences were noted in the case of submaximal and maximal exercises, despite the fact that the respective periods on the treadmill for individuals in good physical condition were three to six times as long as for those in poor shape.

Postoperatively, one group of nineteen patients was placed at complete bed rest for from six to thirteen days. Except for some individuals in excellent physical condition, the patients showed much higher maximal blood lactate levels with exercise during convalescence than was observed precoperatively. Very rarely were the readings back to the precoperative level by the twentieth postoperative day. The changes in the quantity of lactate in the postexercise urine specimens followed the same trend in some instances the values remaining elevated for as long as sixty days after operation. It is of interest that the lactate studies continued to show abnormal changes postoperatively long after the results of the tests of liver function and of circulatory and respiratory efficiency had returned to precoperative levels.

Other groups of patients subjected to the same operative loads were placed on regimens involving early ambulation. Except for occasional patients initially in poor physical condition, these individuals showed, during convalescence, smaller increases in maximal blood lactate levels and lactate content of the urine with exercise, as compared with the precoperative readings, than were observed for the patients subjected to a period of postoperative bed rest.

It is concluded that the magnitude of the blood and urine lactate changes produced by exercise is definitely influenced by the state of physical fitness of the individual. Furthermore, lactate studies are of value in the measurement of the length of convalescence following surgical operations and in the evaluation of various therapeutic regimens used to reduce this period.

28 PORTAL CIRRHOSIS OF THE LIVER A CLINICAL AND FUNCTIONAL STUDY

WILLIAM L. RICKFITS, M.D. (BY INVITATION) JOSEPH B. KIRSNER, M.D.,
AND WALTER L. PALMER, M.D., CHICAGO, ILL.

Fifty cases of portal cirrhosis of the liver were studied by biopsy and tests of hepatic function. The fifty cases were divided into three groups.

Group I included fourteen patients free of symptoms, except one who had hematemesis and melena, but with physical findings suggesting the presence of cirrhosis such as hepatomegaly, splenomegaly or collateral circulation of the abdomen. In two, the cirrhosis was first noted at laparotomy. The presence of cirrhosis was established by histologic examination. The alterations in hepatic function were minimal or absent, the bromsulphalein test was the most consistently abnormal.

Group II included twenty three patients in whom signs and symptoms of moderate degrees of hepatic disease were present. Fibrosis and hepatocellular changes were noted histologically in all. Function tests in this group were uniformly abnormal. Repeated studies of hepatic function were made in nineteen of the group during the course of medical management. There was no significant change in two, improvement was marked in fifteen, and the test ultimately yielded normal results in two.

Group III included thirteen patients with marked jaundice and other symptoms of hepatic dysfunction requiring hospitalization. The function tests were markedly impaired in all. Fibrosis and severe parenchymal changes were noted histologically in ten of the thirteen. Four were admitted desperately ill and died soon after hospitalization. Subsidence of symptoms, marked improvement in hepatic function and regeneration of the liver parenchyma were observed accompanying medical management in nine. The symptoms disappeared completely in six of these, two improved greatly and one has improved and has no symptoms other than an acquired hemolytic anemia.

The following impressions were gained: (1) Abnormalities of hepatic function in portal cirrhosis depend upon the alterations of the parenchyma. (2) Fibrosis of the liver per se does not change the tests of liver function. (3) Portal cirrhosis may be present without detectable abnormality of hepatic function, and (4) portal cirrhosis is not necessarily a progressive disease.

29 SERIAL SERUM CHOLINESTERASE DETERMINATIONS IN LIVER DISEASE

L. J. VORHAUS, M.D., H. H. SCUDAMORE, M.D., G. J. GABUZOA, M.D., G. R. MOREA, M.D., M. A. MALONEY, M.D. AND R. M. KARR, M.D.
CHICAGO, ILL.

(INTRODUCED BY ROBERT W. KEETON, M.D.)

It has long been known that the cholinesterase activity of the serum is abnormally low in patients with disease of the liver and its determination has been suggested in the past as an index of liver function. However, because of the difficulty in performing determinations of serum cholinesterase activity, and because of the wide range of normal values obtained, such determinations have not become popular. The recent development by Michel of a simple potentiometric method for the determination of cholinesterase activity now makes

this measurement a practical clinical tool. The method measures the change in pH due to the liberation of acetic acid in the hydrolysis of acetylcholine by cholinesterase.

To date serum cholinesterase activity has been estimated in forty-two patients and serial determinations have been made in twenty-six of these patients with liver disease, as well as in four normal subjects. In patients with liver disease serial determinations have correlated well with changes in clinical status at times when a battery of currently accepted liver function tests failed to show significant changes.

Serial determinations are reported of the serum cholinesterase activity of seven patients with cirrhosis of the liver and three healthy controls living in a metabolic ward for periods of 70 to 240 days. Determinations were made three times weekly before, during, and after intravenous therapy with human serum albumin containing less than 0.3 Gm. of sodium in each 25 Gm. of albumin. The total doses of albumin ranged from 125 Gm. in a three-day period to 3,600 Gm. in three periods totaling forty-seven days. It was found that six of the seven patients with liver disease showed a significant rise in the serum cholinesterase activity together with subjective and objective clinical improvement. In all of these cases the serum cholinesterase activity began to rise toward normal levels before improvement was detectable by any other laboratory means employed. Results suggest that serial determinations of cholinesterase activity afford a more sensitive index to slight changes in hepatic function than any of the other tests used in this study (that is, cephalin flocculation, thymol turbidity and flocculation, BSP excretion, serum bilirubin, immediate and total, two-hour Watson urinary urobilinogen, prothrombin time, total proteins with A/G ratio).

Studies are in progress on the rate of regeneration of serum cholinesterase activity following its destruction by di-isopropyl fluorophosphate. In thirteen patients with liver disease, as well as in four healthy controls, the return to serum cholinesterase activity to pretest levels has taken approximately four weeks, the healthy controls starting at and returning to a higher value than the patients.

30 ANTIDIURETIC ACTIVITY OF URINE IN ACUTE HEPATITIS

J. L. SIMS, MADISON, WIS.

(INTRODUCED BY O. O. MEYER, M.D.)

This study was undertaken in an attempt to confirm the presence of an antidiuretic factor in the urine of patients with liver disease and to elucidate the mechanism of its appearance.

Daily twenty-four hour urine specimens were obtained from nine patients with acute infectious hepatitis, one with serum hepatitis, and one with an acute febrile and icteric exacerbation of a portal cirrhosis with ascites and edema.

Protein precipitation at pH 4.0 and 80° C. was carried out, the supernatant was dialyzed twenty-four hours against tap water and evaporated to 100 ml. in cellophane sacks before an electric fan.

Assay was by intraperitoneal injection of 0.5 ml. per 100 Gm. body weight into groups of four adult male albino rats hydrated to 5 per cent of their body weight by tap water gavage. Controls received tap water or similar extracts from normal urines intraperitoneally. Urinary output per 100 Gm. of body weight was plotted for three- or five-hour periods and compared with the intake output records and clinical appearance of the patients.

In the early phases of acute hepatitis there was a sharp inhibition of diuresis in the assay animals which paralleled clinical evidences of a tendency to water retention. With beginning convalescence this inhibitory activity lessened and the output of assay animals approached or exceeded the controls. In two instances the first specimen obtained from a patient failed to show antidiuretic activity, although subsequent ones during the early phase of illness did. Similar results were seen over a longer period in the encephalic patient.

Samples of varying activity were assayed on male albino rats made encephalic by prolonged twice weekly injections of carbon tetrachloride. The degree of inhibition of diuresis in this group did not exceed that in simultaneously run normal control animals, and indeed, in about two thirds was slightly less.

Five and eight hour urine outputs from both the control and encephalic animals were extracted in similar fashion being evaporated to 12 ml and re-assayed. These preparations showed no increase in antidiuretic activity as compared with similar recoveries from animals injected with tap water.

These studies confirm Labby's findings of the presence of a factor showing antidiuretic activity in the urine of patients in the early phases of acute hepatitis. They do not support the thesis that failure of hepatic inactivation of a normally formed principle of this nature is the basis of its presence.

31 VITAMIN B₁₂ IN PERNICIOUS ANEMIA AND PUERPERAL MACROCYTIC ANEMIA

FRANK H BETHELL M D MURIEL C MYERS M D (BY INVITATION) AND
ROSALIE B NELIGH, M D (BY INVITATION) ANN ARBOR MICH

Four patients with pernicious anemia in relapse were treated with vitamin B₁₂ for periods of ten to twenty weeks. Intramuscular injections of 1 µg of B₁₂ were given daily during the period of the reticulocyte response with subsequent treatments at varying intervals up to twenty five days. Doses were adjusted so that the equivalent of 1 µg per day would be received. Three of the patients had maximum reticulocyte levels and rates of red cell increase which exceeded the expected response following daily injections of 1 U S P unit of liver extract. The fourth patient received 1 mg of the folic acid antagonist, Aminopterin† daily for two days prior to B₁₂ administration and for the first fourteen days of treatment with B₁₂. The reticulocyte response was delayed and suboptimal. When aminopterin was discontinued a second reticulocyte response occurred with rapid elevation of red cell count. All four patients attained normal hematologic values after six to eight weeks.

Three patients had nervous system involvement. Following B₁₂ therapy there was relief of paresthesias and decrease in ataxia. Glossitis was troublesome in three patients and disappeared promptly on institution of treatment.

A girl aged 19 years was seen two months after delivery of a normal infant. The presenting features were severe anemia, intense glossitis, stomatitis and vulvovaginitis. For at least two years she had received an extremely poor diet. Red cell count was 1,500,000 with macrocytosis, leucopenia and megaloblastic marrow. Gastric contents contained hydrochloric acid. Intramuscular injections of 1 µg of B₁₂ for ten days failed to produce hemopoietic or clinical responses. Anemia and leucopenia became more severe and mucous membrane lesions progressed. Megaloblastic marrow reaction persisted. Subsequent treatment with folic acid 10 mg daily by mouth was followed by conversion of

marrow picture, reticulocyte response, increase in erythrocyte and leucocyte values, and rapid subsidence of stomatitis and vulvovaginitis

Assays of feces of four patients with untreated pernicious anemia revealed high contents of growth-stimulating factor for *Lactobacillus lactis* Dozier, the test organism for vitamin B₁₂*. The content of B₁₂ equivalent ranged from 3 to 18 μ g per gram of dried feces. Thus the daily output of B₁₂ by patients with pernicious anemia appears to be many times greater than that necessary to produce remission when introduced parenterally. This suggests that in pernicious anemia there may be defective absorption of vitamin B₁₂ derived either from dietary sources or by intestinal bacterial synthesis.

32 STUDIES ON GLOBIN AND PORPHYRIN METABOLISM MADE WITH C¹⁴ AND N¹⁵

MOISES GRINSTEIN, PH D (BY INVITATION), M D KAMEN, PH D (BY INVITATION), AND CARL V MOORE, M D, ST LOUIS, MO

Three different forms of tracer-tagged glycine have been used to label hemoglobin. Shemin and Rittenberg employed glycine containing N¹⁵ to demonstrate that this amino acid serves as a nitrogenous precursor of protoporphyrin, a small amount of the N¹⁵ was also incorporated in the total cell protein. They followed the N¹⁵ content of heme carefully and found that (a) the labeled protoporphyrin within red cells does not participate in the dynamic metabolic state, (b) is not re-utilized for heme formation when red cells are destroyed, and (c) serves as a reliable index of the length of life of the erythrocyte. Altman and associates, using methylene labeled glycine (C¹⁴), have shown that the alpha carbon of glycine is utilized for the biosynthesis of hemoglobin protoporphyrin; a relatively small amount of C¹⁴ is incorporated into globin. When glycine labeled with C¹⁴ in the carboxyl position is fed to animals, the C¹⁴ is built into globin but not into protoporphyrin (Grinstein and co workers). The first and last of these three methods of tagging hemoglobin were used in the experiments described below to study globin and porphyrin metabolism.

Glycine containing C¹⁴ in the carboxyl group was fed to two dogs and to one rat. In each instance, the C¹⁴ appeared in the globin portion of hemoglobin but could not be demonstrated in the heme. The concentration in globin rose rapidly in the dogs during the first few days, remained relatively constant until the sixty-fifth and eightieth days, respectively, and then fell to very low levels. The shape of the curve obtained was very similar to that found by Shemin and Rittenberg for heme labeled with N¹⁵. The results indicate that the globin of intact erythrocytes (1) remains within the cell during its life span without participating in the dynamic protein interchange characteristic of nucleated cells and (2) is apparently not utilized again for new hemoglobin formation once the cell is destroyed.

In the second series of experiments, 5.6 Gm of glycine tagged with 27.7 per cent excess N¹⁵ was fed to one dog which had previously been made anemic by bleeding. From blood obtained at intervals during the following thirty-four days, crystalline protoporphyrin 9 dimethylester was isolated and found to be tagged with the isotope (0.72-0.96 atom per cent excess N¹⁵). During the first twenty days of the experiment, coproporphyrin I (tetramethylester) was isolated from the urine and feces of this animal, it contained N¹⁵ in a relatively high concentration (1.1 atoms per cent excess). On the thirty-fourth day, the dog was bled to death, and the total volume of red blood cells removed was trans-

*Performed by Dr O D Bird Parke Davis & Co

fused into a second anemic dog. The following day, crystalline protoporphyrin 9 isolated from the blood of the recipient animal contained 0.40 atom per cent excess N^{15} . An acute anemia was then induced with phenylhydrazine. Coproporphyrin I isolated from the combined urine and feces during this period had no demonstrable N^{15} (less than 0.03 atom per cent excess), while the protoporphyrin 9 dimethyl ester isolated at the same time from urine and feces did contain the isotope (0.133 atom per cent excess). On the twentieth day when the animal was recovering from the phenylhydrazine anemia protoporphyrin 9 dimethyl ester crystallized from its blood had N^{15} in a concentration of 0.132 atoms per cent excess. This experiment has not yet been repeated. Conclusions therefore must be regarded as being *preliminary*. The data suggest that coproporphyrin I is formed as a by product during the biosynthesis of hemoglobin and is not derived from hemoglobin catabolism. This result was expected. More surprising, however, was the increased concentration of N^{15} in the protoporphyrin 9 from the excreta of the recipient dog, a finding which suggests that the excreted protoporphyrin 9 might, in phenylhydrazine anemia at least be a derivative of hemoglobin degraded during the hemolysis. Free erythrocyte protoporphyrin of the red cells would be another possible source of the fecal protoporphyrin 9.

33 THE COAGULATION DEFECT IN THROMBOCYTOPENIC PURPURA

ARMAND J. QUICK, M.D., JACOB N. SHANBERG, M.D. (BY INVITATION), AND
MARIO STEFANINI, M.D. (BY INVITATION) MILWAUKEE, WIS.

In thrombocytopenic purpura the platelets are reduced, the bleeding time is prolonged, clot retraction is absent, spontaneous hemorrhages occur, and petechiae and other manifestations of vascular fragility appear. The coagulation time characteristically is nearly always normal. This has led to the tacit acceptance that no true coagulation disturbance is present in this disease and that platelets are of secondary importance in the coagulation mechanism.

Recent findings concerning the platelets makes it possible to offer a new concept of coagulation and thereby to formulate a better explanation for the basic hemostatic dysfunction in thrombocytopenic purpura. It is now certain that platelets are indispensable for coagulation. When these cells disintegrate they liberate an enzyme which immediately acts on the precursor of thromboplastin (thromboplastinogen), converting it to its active form. This product acts on the prothrombin complex to form thrombin. When platelets are diminished, the conversion of thromboplastinogen is delayed and therefore the activation of prothrombin is abnormally slow. This is easily measured by the prothrombin consumption test which furnishes a better estimate of the true coagulability than the coagulation time since the latter is merely an empirical measurement of the time required for the formation of enough fibrin to meet an artificially set standard such as sufficient solidity to hold the blood when the test tube is inverted.

The prothrombin consumption is markedly reduced in severe thrombocytopenic purpura. The coagulation time may however even be shorter than normal and therefore mask the basic coagulation disturbance. In hemophilia the prothrombin consumption likewise is very low. Thus, the basic defect in adequate formation of thrombin is common to both hemophilia and thrombocytopenic purpura. Yet the clinical manifestations of these two diseases are distinctly different. One finds moreover occasionally a persistent low platelet count without a concomitant spontaneous hemorrhagic diathesis and a prolonged bleeding time. It is likely therefore that the characteristic features of

thrombocytopenic purpura such as the petechiae, the mucous membrane oozing of blood, and the prolonged bleeding time are not due directly to the deficiency of platelets but are caused by a factor affecting the vascular structure, particularly the capillaries, and this is superimposed upon the basic coagulation defect. In summary, the poor prothrombin consumption and the defective clot retraction are due directly to lack of platelets, while the spontaneous hemorrhagic tendency is attributable to a vascular factor whose action is accentuated by the coagulation defect.

34 A STUDY OF THE PLASMA DEFECT IN PATIENTS WHOSE BLEEDING IS TEMPORARILY CONTROLLED BY PROTAMINE SULFATE OR TOLUIDINE BLUE

J GARROTT ALLEN, M D (BY INVITATION), LEON O JACOBSON, M D, AND
BURTON J GROSSMAN, B S (BY INVITATION)
CHICAGO, ILL

The anticoagulant action of heparin is rapidly overcome upon addition of protamine (salmine sulfate). Normally when a standard amount of heparin is added to a constant volume of blood (0.09 mg of liquid heparin per milliliter of blood), its action is regularly overcome and clotting occurs with a standard amount of protamine sulfate, 0.120 mg. In certain hemorrhagic states, most but not all of which are associated with thrombocytopenia, considerably more protamine may be required before clotting occurs. These patients generally have a prolonged Lee-White clotting time, the clotting of which is preceded by a gel-like formation. This syndrome has been observed in patients with leukemia who are bleeding, patients under extensive nitrogen mustard and/or P³² therapy, a small percentage of patients with idiopathic thrombocytopenic purpura, in three patients who received heavy "spray" x-radiation, in some patients who bleed abnormally but in whom the platelet count and other known clotting studies are normal, and in certain patients with menorrhagia.

The nature of the defect is not known. It may be due to the release of heparin or heparin-like substances since the defect measured in this heparin-protamine titration procedure may be temporarily corrected by the administration of protamine sulfate or toluidine blue. The possibility of a decrease of heparin co-factor associated with a heparinemia (?) has been explored. This possibility was suggested by the fact that the amount of heparin required to alter the heparin-protamine titration in normal patients or dogs renders the Lee-White clotting time incoagulable. This is in contrast to the defect seen in the patient with this bleeding syndrome whose clotting time may be only moderately prolonged but whose heparin-protamine titration is remarkably altered. However, since in vivo rapid intravenous heparin (0.25 to 0.50 mg per kilogram) administration in such patients or in irradiated dogs has a much greater effect upon the whole blood clotting time than usually occurs, it appears unlikely that the heparin co-factor is abnormal.

Since many of the plasma and tissue proteins are antiheparins, it may be that the associated protein changes in some of these disorders in part account for the disturbance through the release of heparin or heparin-like substances, which may then affect the clotting system. Present studies suggest that a diminution in the antiheparins of plasma and/or an increase, relative or actual, of the plasma heparinoid substances are the systems most likely affected. More data are required before a final conclusion can be drawn.

3. CHANGES IN BLOOD AND BONE MARROW IN ACUTE LEUCEMIA INDUCED BY AMINOPTERIN

J M STICKNEY, M D A B HAGEDORN, M D S D MILLS, M D, AND
TALBERT COOPER, M D
ROCHESTER, MINN

(INTRODUCED BY F J HECK, M D)

4 Aminopteroyl glutamic acid (Aminopterin) was administered to eight men and children with acute leukemia diagnosed by study of the blood and bone marrow. Remissions in the clinical course of the disease as well as improvement in the blood and bone marrow were observed in some instances, although many patients made no response to the drug. Toxic manifestations included stomatitis, diarrhea, alopecia, deafness and temporary aplasia of the bone marrow. In an attempt to prevent these toxic effects vitamin B complex, crude liver, and folic acid were used.

When the response to treatment was favorable changes in all the elements of bone marrow were conspicuous. The myeloid cells assumed a more normal pattern and in lymphatic leucemia the lymphocytes decreased and became more mature. The increase in erythropoiesis was striking. When folic acid or liver extract was not administered the marrow sometimes contained megaloblasts and hyperlobulated polymorphonuclear leucocytes. Liver or folic acid prevented megaloblastic changes or caused them to disappear after they were established.

These observations are further confirmation of the theory that Aminopterin has an action antagonistic to that of folic acid. The length of time over which the clinical observations have been made does not permit any definite conclusions about the eventual effect of Aminopterin in acute leucemia.

ADDITIONAL ABSTRACTS

36 THE MINIMAL SODIUM DIET A CONTROLLED STUDY OF ITS EFFECT UPON THE BLOOD PRESSURE OF AMBULATORY HYPERTENSIVE SUBJECTS

MILTON LANDOWNE, M D, WALTER THOMPSON, M D (BY INVITATION), AND
BARBARA RUBY, B S (BY INVITATION), CHICAGO, ILL

The administration of a diet rigidly restricted in sodium may influence the habits and reactions of the patient profoundly, altering blood pressure through mechanisms unrelated to the effect of sodium restriction per se. A controlled evaluation of the factors attendant upon the use of this diet is necessary, particularly in the nonhospitalized patient. Accordingly, twenty-one hypertensive subjects were placed on a calorically adequate diet estimated to contain less than 300 mg of sodium per day and were followed for approximately eighteen weeks. Blood pressures were obtained in the clinic by a constant technique, and twenty-four hour urine collections were made once a week. All subjects received medication, consisting either of 4 Gm of NaCl a day or of identical appearing placebos. After each six-week period the medication was either changed or continued according to prearranged schedules, initially selected at random for each subject by the pharmacist.

The experiment thus consisted of three periods, differing only in that during one (or two) period(s) supplemental sodium chloride was administered, while in two (or one) period(s) the sodium intake remained at a bare minimum. The subject, whose cooperation was solicited, was unaware of the nature of the medication, and during the study the investigators did not know which medication was being taken.

Results—Data from which evaluation of the effect of rigid sodium restriction upon blood pressure could be based were available from only eight of the subjects. The criteria for their selection required that the twenty-four hour urinary sodium average below 500 mg for at least one period and over 1,000 mg for at least one period. For these subjects the average of the blood pressures taken during rigid sodium restriction was lower than the average during the periods of added sodium, by 4.72 mm Hg diastolic (range, 18.5 to -8.02) and 4.96 mm Hg systolic (range, 22.15 to -7.90).

All twenty-one subjects yielded data for at least two periods of a like order of sodium excretion, from which the variances of the blood pressures for the group were determined. On this basis, the probability that the experimentally observed differences could be due to chance is less than 1 in 50 for the diastolic values ($t = 3.01$) and less than 1 in 20 for the systolic values ($t = 2.36$).

Conclusions—

- 1 A diet rigidly restricted in sodium is difficult to administer successfully to ambulatory hypertensive subjects.
- 2 A difference of less than 5 mm Hg in average blood pressure was observed, ascribable to the effect of NaCl restriction alone.
- 3 This difference is statistically significant.

37 THE EFFECT OF DESOXYCORTICOSTERONE ACETATE AND PROPYLENE GLYCOL IN EXPERIMENTAL RENAL HYPERTENSION

W D DAVIS, JR, M D (BY INVITATION), ALBERT SEGALOFF, M D, AND
WILLIAM JACOBS, M D (BY INVITATION) NEW ORLEANS, LA

Experiments performed to determine the blood pressure response in renal hypertensive and normal dogs revealed the following (1) a small but definite pressor effect from intravenous administration of propylene glycol in unanesthetized dogs (2) no additional effect from intravenous administration of desoxycorticosterone acetate dissolved in propylene glycol (3) no pressor effect from intravenous administration of desoxycorticosterone glucoside and (4) a similar and sustained pressor effect from continued subcutaneous administration of desoxycorticosterone acetate in sesame oil in both normal and hypertensive dogs

Initial experiments were performed on mongrel dogs trained for blood pressure determinations by femoral arterial puncture. Three were made hypertensive by renal arterial clamps or perineal silk wrappings. Approximately eighteen months were allowed as the postoperative stabilization period. Desoxycorticosterone acetate in daily doses of 0.15 to 1.25 mg. per kilogram of body weight was given for a total of eight periods of six weeks each in three hypertensive and two normal dogs. Blood pressure rises of 25 to 50 mm. Hg were observed in seven instances. These were sustained and disappeared within two to four weeks of withdrawal of the drug. Repeat courses of the drug in the same animals produced shorter and less pronounced elevations of blood pressure which tended to return to control level before the drug was discontinued. In some instances the post treatment levels were 20 to 30 mm. Hg lower than control levels. There were no essential differences between the responses of the hypertensive and the normal dogs.

In a second group of experiments propylene glycol and desoxycorticosterone acetate in propylene glycol were given intravenously to three hypertensive and three normal dogs. In twenty six determinations no significant difference between normal and hypertensive blood pressure responses to the two preparations was noted. Two cubic centimeters of propylene glycol regularly produced a rise of 15-30 mm. Hg in both groups. The response was unchanged by the addition of 5 mg. of desoxycorticosterone acetate.

Aqueous desoxycorticosterone glucoside in dosage of 5 mg. intravenously had no pressor effect in any instance. In an acutely hypertensive dog anesthetized with pentobarbital sodium no significant pressor effects were observed with any of the three preparations.

38 INTRA-ARTERIAL BLOOD PRESSURE CURVES DURING TILTING

A NEW METHOD OF STUDYING HYPERTENSION

ROBERT S GREEN M D (BY INVITATION) ARNOLD IGLAUER M D AND
JOHNSON MCGUIRE M D CINCINNATI OHIO

Previous studies demonstrated that the blood pressure at the level of the aortic arch invariably rose during a tilt from 20 degrees erect to a 45 degree head down position and fell during the return tilt to the 20 degree erect position. These alterations were due to a change of the effect of the force of gravity on the central blood column.

These changes apparently acted as intra-arterial stimuli to blood pressure regulatory mechanisms. In normal subjects, maintained in the altered position, the primary elevation that occurred during the head down tilt was followed by a secondary reflex depressor response, the fall during the erect tilt by a pressor response, whereby the blood pressure returned within eight to eighteen seconds to approximately the initial level, regardless of position.

Similar studies have been completed in a series of fifty nonselected patients with hypertension. Primary mechanical alterations of blood pressure occurred during tilting as in the normal group. However, the secondary response to these alterations varied.

The elevation during the head down tilt was followed by four types of response:

- 1 Delayed depressor the blood pressure rose further before falling
- 2 Decreased depressor the blood pressure remained at an elevated level for a prolonged period
- 3 Normal depressor
- 4 Increased depressor the pressure shortly after the head down tilt was lower than in the semierect position. Patients with this type response usually complained of dizziness on bending over.

The fall during the erect tilt was also followed by four types of response:

- 1 Increased pressor the blood pressure immediately surged beyond, then gradually returned to the initial level of the 20 degree erect position
- 2 Normal pressor
- 3 Decreased pressor the blood pressure remained lower than the initial erect level for a prolonged period
- 4 Delayed pressor the blood pressure fell further before returning to the initial erect level

Patients with the two latter types of response usually complained of dizziness on arising suddenly.

Various combinations of pressor and depressor response occurred in individual patients, that is, normal depressor with increased pressor, decreased pressor with normal pressor, etc. In a given patient the combination of response remained constant on successive tiltings.

In normal subjects the heart rate invariably slowed following the head down tilt. In some hypertensive patients the heart rate slowed as in the normal, in others it did not change.

It is hoped that this method of study of the cardiovascular reflexes will offer a means of classifying hypertension and indicate possible approaches to treatment.

39 ANTIBODIES AGAINST RENIN AND "SUSTAINED PRESSOR PRINCIPLE" PRODUCED BY INJECTIONS OF KIDNEY EXTRACTS

O. M. HELMER, PH. D., R. E. SHIPLEY, M. D. (BY INVITATION), J. D. PEIRCE, M. D. (BY INVITATION), AND K. G. KOHLSTADT, M. D., INDIANAPOLIS, IND.

Intramuscular or intraperitoneal injection of various kidney extracts into several animal species caused the appearance in the sera of a substance or substances capable of destroying or "neutralizing" renin and the "sustained pressor principle."

Extracts prepared from hog kidneys were administered over the period of a year to a series of ten hypertensive patients. Although antibodies against

hog renin and hog 'sustained pressor principle' were formed in the serum of these patients, the antibodies failed to neutralize human renin or 'sustained pressor principle'. These extracts which did not possess irritating and shock producing properties caused no lowering of blood pressure in the patients.

Of the several types of animals used only the dog produced antibodies to its own renin when injected with heterologous kidney extracts.

40 EFFECTS OF SPLANCHNICECTOMY ON BLOOD PRESSURE AND ON CARDIAC AND RENAL FUNCTION

S W HOOBLER, M D, J T MANNING, M D (BY INVITATION) S G MCCLELLAN, M D (BY INVITATION) HENRY REUFERT JR M D (BY INVITATION), AND MAX M PEET M D (BY INVITATION)
ANN ARBOR MICH

One hundred eight hypertensive patients were studied before and ten to sixteen months after supradiaphragmatic splanchnicectomy (Peet). Thirty one control patients acceptable for the operation who did not undergo surgery were re-examined ten to eighteen months later under similar conditions. These patients were comparable to the operated group in age, sex, height of blood pressure and duration of hypertension and were treated by the usual medical methods including mild sedation in some cases. Table I presents the significant differences in the observations on the two groups at the time of follow up examination.

TABLE I

INITIAL STATUS OF PATIENT	POST SPLANCHNICECTOMY SERIES		CONTROL SERIES	
	NUMBER	% IMPROVED	NUMBER	% IMPROVED
Casual diastolic blood pressure exceeding 110 mm mercury	80	21*	25	0
Cardiac enlargement present by teleroentgenogram	15	20	5	0
Electrocardiographic abnormality present	81	22	9	0
Headaches	84	92	20	50
Irritability and nervousness	73	72	16	25
Dizziness	50	76	13	54

*More than 20 mm decline in casual diastolic blood pressure at follow up visit was considered improved.

Only twelve of the patients had a diastolic blood pressure below 90 after operation. We believe, however, that there were definite evidences in certain of the other hypertensive patients that the operation improved their clinical status when they were compared with the control subjects. This result was accomplished with a minimum postoperative disability. Patients left the hospital ten to twelve days after operation and were able to resume full activity in two to three months.

Sixteen of the splanchnicectomized patients who had had a 20 mm decline in diastolic blood pressure were compared with seventeen patients who had experienced slight increases in pressure one year after operation. In general the subjects in the group which improved were younger, had a higher initial blood pressure, contained more females and showed a greater fall in blood pressure after tetraethylammonium than did those in the group showing poor results.

In thirty four patients renal hemodynamics were studied before and at various time intervals after operation. Renal blood flow (para-aminohippurate clearance) was usually unchanged but filtration rate (mannitol or thiosulfate

clearance, tended to fall with a consequent decline in filtration fraction. In some patients with a 20 per cent postoperative reduction in mean blood pressure the renal blood flow was maintained and there was a consequent decline in renal resistance suggesting some postoperative renal vasodilatation.

41 THE ARTERIOLES OF THE SKIN IN ESSENTIAL HYPERTENSION

EDG R A HINES JR, M D, ROCHESTER MINN, AND EUGENE M. FARBER, M D
(BY INVITATION), SAN FRANCISCO CALIF

It is generally accepted that a diffuse disturbance of the arterial side of the vascular system exists in hypertension. Curiously enough the cutaneous arteriolar beds in people with essential hypertension have not been studied adequately. For this reason we felt that a controlled study of the arteriolar bed of the skin in a group of persons who had essential hypertension might be of value.

Material for this study was obtained from the upper arm lumbar region and calf or foot of two persons who had normal blood pressure and from seventy persons who had moderate to severe essential hypertension. The skin was obtained by means of excision and punch. All the material in the hypertensive group was secured from living people. The youngest person with hypertension was 29 years old, the oldest person was 80 years of age, the mean age was 44 years. Of the fifty-two specimens of skin removed from persons who had normal blood pressure forty were taken from living people and twelve were obtained at necropsy.

Sections for microscopic study were made. A Bausch and Lomb micrometer eyepiece was used over a high-power objective which produced a magnification of 430 times (43 x 10). With this instrument the average thickness of the wall of the vessel and diameter of the lumen were measured. We studied every slide from left to right and made measurements of the first four arterioles we saw in each slide.

A measurable thickening of the arteriolar wall and a decrease in the wall-to-lumen ratio as compared with normal were found in vessels of the skin of patients with hypertension. The average of the wall-to-lumen ratio of the arterioles of fifty-two persons with normal blood pressure was 1.214, among seventy persons who had essential hypertension it was 1.157. Not all arterioles were equally affected in the same case.

Qualitative changes were also present. Hyperplasia of the nuclear elements of the media and thickening of the inner elastic lamina appeared to be the most common changes. Occasionally, complete occlusion of the lumen occurred. Although the arterioles in the skin of persons who had malignant hypertension were more profoundly altered than were those of persons who had other types of hypertension, equally severe qualitative changes were present in the arterioles of a number of persons who had the other types of hypertension. Four patients with normal blood pressure had medial hypertrophy of the arteriolar wall.

42 RETINAL ARTERIOVENOUS NICKING

II A LONG-TERM STUDY OF THE DEVELOPMENT OF ARTERIOVENOUS NICKING IN PATIENTS WITH HYPERTENSION

SAMUEL A. SHELBURNE, M D, DALLAS, TEXAS

We reported our studies on the significance of various stages of retinal arteriovenous nicking in patients with hypertension before this society in November, 1939. We have now re-studied a group of these same patients after eight

to ten year intervals and have followed for the first time the development of arteriovenous nicking from the earliest stages to the latest. We have thus shown for the first time that the so called early lesion actually develops into the late lesion. The importance of distinguishing these lesions one from the other will be emphasized. Color drawings of unusual clarity will be presented showing the various types of arteriovenous nicking and other retinal arterial changes found in hypertensive patients.

43 THE INSULIN TOLLRANCE OF THE HYPERTENSIVE PATIENT

GEZA DL TARATS M.D., AND JACK LASLER M.D. (BY INVITATION)
CHICAGO, ILL.

The insulin tolerance of fifty hypertensive patients have been studied. One tenth of a unit of insulin per kilogram of body weight was injected intravenously and blood sugar levels were determined at 15, 30, 60, 90 and 120 minutes after each injection. A normal response was characterized by a drop of the blood sugar to about 50 per cent of the fasting level at thirty minutes followed by a return to normal in the next two hours.

In the present series of fifty patients 16 per cent showed complete and 8 per cent showed a partial resistance to the intravenous dose of insulin. This insulin response was used to measure the presence of corticoadrenal activity. Such hyperactivity may be one of the causes of immediate failure following splanchnic nerve section although delayed improvement may occur.

In addition, our previous observations that the insulin resistant diabetic patient becomes insulin sensitive after splanchnic nerve section was observed in two patients with diabetes in this series.

44 PALPITATION

EDWARD MASSIE, M.D., AND HERBERT C. WIGAND, M.D. (BY INVITATION)
ST. LOUIS, MO.

Palpitation is a symptom usually much more alarming than serious. It consists of an unpleasant sensation of the heart's action whether slow or fast, regular or irregular. It more frequently does not indicate primary physical but rather a psychic disturbance.

Four hundred patients from Barnes Hospital, private practice and the Washington University Clinics presenting various degrees of palpitation were studied to determine the clinical characteristics of this condition. Of this group approximately half were clinic and the other half hospital patients. Sixty four per cent were females and 36 per cent males. Palpitation was noted as a primary complaint in approximately half the entire group and as an accessory complaint in the remainder. The commonest age incidence was in the group from 40 to 50 years and next in order of frequency were the sixth and fourth decades. One hundred ninety five (49 per cent) had a severe form of palpitation, 183 (46 per cent) had this symptom to a moderate degree and 22 (5 per cent) considered it mild. In women the complaint appeared more consistently in the severe form.

Of the 152 patients with cardiac and vascular disease the principal etiologic factors included arteriosclerosis and hypertension (53 per cent), hypertension alone (18 per cent) and rheumatic fever (7 per cent). Seventeen per cent of the total group had extracardiac conditions of diverse type. The arrhythmias encountered in the 325 patients who had electrocardiograms in

cluded ventricular extrasystoles (22 per cent), auricular fibrillation (12 per cent), sinus tachycardia (9 per cent), sinus bradycardia (6 per cent), and very few instances of auricular extrasystoles, auricular flutter, and paroxysmal auricular tachycardia. Two patients had complete heart block. Two hundred twenty-seven patients had basal metabolism tests, only three had rates above +30 per cent, and nine were in the range from +20 to +30 per cent. Only six patients had clinical hyperthyroidism.

Two hundred twenty-eight (57 per cent) of the entire group presented primary nervous complaints, and of these patients, 57 per cent had a definite anxiety state, 22 per cent were typical of neurocirculatory asthenia, 12 per cent presented prominent menopausal symptoms, and 9 per cent were psychotic. Analysis of the cases revealed no significant evidence that such factors as anemia, fever, digitalis, or smoking had any direct connection with this symptom. Excessive intake of alcohol or coffee seemed to produce marked palpitation. Undoubtedly the most common etiologic factor was the presence of a significant anxiety state, and when this was associated with emotional stress or fatigue, palpitation became not only a frequent, but also a most troublesome symptom.

45 OBSERVATIONS ON ONE HUNDRED PATIENTS WITH MYOCARDIAL INFARCTION WHO SURVIVED UP TO SIX YEARS

G. Y. MILLS, M.D. (BY INVITATION), F. CISNEROS, M.D. (BY INVITATION), AND
L. N. KATZ, M.D., CHICAGO, ILL.

We have recently had the opportunity to make a follow up survey on 100 patients who had survived an acute myocardial infarction for from one to six years.

Our patients represented a cross section of the population with varied occupations, interests, and income. Most of the patients had returned to their former jobs. In most instances the younger patients were more regularly able to resume a full share of previous activity after recovery than the older ones.

In general the trend was toward a higher blood pressure at follow up than that which existed at the time of infarction. Males were more prone to have hypertension with the greatest incidence on the fifth decade. Hypertension was the most frequent finding among patients with little electrocardiographic restitution.

Angina pectoris occurred four times as frequently in males as in females, with the greatest incidence in the sixth decade. There appeared to be no relationship between angina pectoris and the amount of electrocardiographic restitution.

Heart failure was seen most frequently in patients in the sixth decade. Almost all of these patients showed little electrocardiographic restitution.

Combinations of angina, hypertension, and heart failure were most frequent among males than females, especially in the fifth and sixth decades. None of the patients with complete electrocardiographic restitution had a combination of angina, failure, or hypertension.

More than five times as many males as females were "asymptomatic" the greatest incidence was in the fourth decade. Patients with previous lateral or atypical infarction electrocardiographic patterns were most likely to be asymptomatic. Approximately two-thirds of the asymptomatic patients had no disturbances of conduction, rhythm, or voltage at the time of their infarction.

46 INTRAVENOUS CATHETERIZATION OF THE HEART IN THE DIAGNOSIS OF CONGENITAL HEART DISEASE

DOY W CHAMMAN, M D, LLOYD J GUGLE M D (BY INVITATION)
HOUSTON, TEXAS

Recent advances in surgical alteration or correction of certain congenital defects of the heart and great vessels make it imperative that more accurate diagnosis of such lesions be made. Intravenous catheterization of the heart has been a useful aid to ascertain the condition in patients suspected of having such congenital abnormalities.

A 6 French or 9 French special catheter is introduced into the median basilic vein and passed under fluoroscopic control via the subclavian vein and superior vena cava into the right side of the heart and into the pulmonary artery and its branches. The oxygen content of samples of blood are obtained at various sites and should not differ normally by more than 1-9 volumes per cent. Pressures in the various sites are recorded by means of a Hamilton manometer.

This procedure has been used in 58 patients with or suspected of having congenital defects of the heart or great vessels. The results illustrate its value to ascertain whether or not the patient has a defect to indicate the operability when defects are discovered and to suggest the prognosis.

In cases of auricular septal defect the oxygen content of the blood from the right atrium is greater than that in the vena cavae. In patients with ventricular septal defects, a significant increase in oxygen content in the blood from the right ventricle is demonstrated when compared with that in the atrium. Septal defects may also be demonstrated by passing the catheter through the defect into the left side of the heart. Patent ductus arteriosus is diagnosed by finding an increase in oxygen content of blood from the pulmonary artery as compared with the right ventricle and occasionally by an increased pulmonary arterial pressure. Cases of cyanotic congenital heart disease are presented showing the usual absence of left to right shunt. Cyanotic patients with increased pressure in the right ventricle or pulmonary artery are discussed. Combined lesions such as cyanotic congenital heart disease with patent ductus arteriosus may be found and patients with such abnormalities are described. Several patients who were suspected of congenital defects but in whom the catheterization studies were normal are described. A case in which a pulmonary vein was found to empty into the right (?) or common (?) atrium is reported. Complications of the procedure including premature ventricular contractions, phlebitis and venospasm, are discussed.

47 DIETARY AND HORMONAL INFLUENCES IN EXPERIMENTAL ANURIA

G MASSON, PH D (BY INVITATION) A C CORCORAN, M D, AND
IRVINE H PAGE, M D CLEVELAND OHIO

The importance of diet in the treatment of uremia has been recently emphasized by Borst. The present study was devised to test experimentally the effects of high iso caloric (9 Cals per 100 sq cm body surface per day) carbohydrate fat and protein diets and of the provision of hormones (desoxy corticosterone acetate and free testosterone 5 mg daily of aqueous suspension) on survival times and azotemia (blood urea N) in bilaterally nephrectomized rats. All treatment was begun at the time of nephrectomy.

Data are summarized in Table I. Survival was definitely improved and azotemia greatly diminished by administration of fat or carbohydrate rather than protein. Survival was somewhat more prolonged and azotemia decreased by administration of carbohydrate rather than fat.

TABLE I MEAN SURVIVAL TIMES AND BLOOD UREA NITROGEN LEVELS IN BILATERALLY NEPHRECTOMIZED RATS

DIET	TREATMENT	NUMBER OF ANIMALS	SURVIVAL TIME (HR.)	BLOOD UREA NITROGEN (MG)	
				AT 30 HR.	AT 48 HR.*
Protein	0	40	42	264	550
	DCA	10	44	263	543
	Testosterone	10	44	240	461
	DCA and testosterone	10	52	281	510
Carbohydrate	0	20	93	112	134
	DCA	9	127	89	131
	Testosterone	9	118	100	130
	DCA and testosterone	9	116	60	90
Fat	0	10	74	135	175
	DCA	9	79	113	167
	Testosterone	9	74	121	173
	DCA and testosterone	9	71	122	166

*In Survivors

Treatment with hormones had no significant effect on survival time regardless of diet, and little effect on azotemia. The data indicate a decrease in blood urea in rats treated with DCA and testosterone on the high carbohydrate diet. It is not established that this change is significant and it is, in any case, evident that it does not improve survival.

These experiments substantiate the beneficial effects claimed by Borst for the treatment of uremia by administration of a high caloric diet, composed largely of carbohydrate. They do not confirm the suggestions of others that hormonal treatment is of value after nephrectomy.

48 PLASMA PROTEIN STUDIES IN CHILDREN WITH RHEUMATIC FEVER

ELIZABETH L. KNAPP, PH.D. (BY INVITATION), JOSEPH W. GIFFEE, M.S. (BY INVITATION), AND ROBERT L. JACKSON, M.D., IOWA CITY, IOWA

Recent statistical studies completed by this clinic revealed an unexpectedly low recurrence rate for a highly susceptible group of young rheumatic children who had received special attention to improve their diets and level of home care. Prior to management, the diets of these children commonly were found to be deficient in protein. The relation between analysis and course of the disease was studied. In general the electrophoretic partition between the albumin and the total globulin fractions confirmed the chemical analysis. The fibrinogen fraction tended to be higher by the electrophoretic method. During the more active phase of rheumatic fever the values for plasma albumin were consistently and markedly decreased, while the values for gamma globulin, alpha globulin and fibrinogen were increased. The changes in the gamma globulin fraction were particularly pronounced. With improvement in the clinical condition of the child the distribution of the plasma proteins shifted toward the normal. Return of the sedimentation rate and the plasma albumin to normal values generally occurred simultaneously, but exceptions were observed.

49 THE RELIEF OF EDEMA IN NEPHROSIS BY PLASMA ALBUMIN AND GELATIN INFUSIONS

WARREN B COOKSEA, MD, DETROIT MICH

Seven patients with advanced nephrotic edema who had been treated by the usual methods without benefit, were given large amounts of salt poor plasma albumin intravenously. There were two failures one of which was a death from infection. Four cases progressed to a satisfactory remission after the marked diuresis which was obtained and one case is still pending. Three patients have been diuresed most satisfactorily with 10 per cent gelatin in distilled water and three have been treated with both gelatin and albumin with very satisfactory results. These experiences strongly suggest that a greatly hastened remission in cases of the nephrotic syndrome is often possible because of the effective diuresis brought about by this method.

50 THE ACTION OF SEVERAL CARDIAC GLYCOSIDES ON EXCITABILITY AND CONDUCTION VELOCITY IN THE DOG HEART

GORDON K MOE MD, AND RAFAEL MENDEZ MD (BY INVITATION)
MEXICO D I

Digoxin (Digitaline Nativelle), lanatoside C ((edilumid) ouabain (Ainaud), and katiophanthoside (Strophosid) were studied in dogs under chloralose anesthesia. The heart was exposed and electrodes attached at various points on the surface of the right atrium and both ventricles to permit measurement of A-V conduction, linear conduction on the surface of the ventricles in response to electrical shocks and the threshold of electrical excitability of both atrium and ventricle. The glycosides were injected at thirty minute intervals in doses calculated to kill the heart in about four hours.

Atrial excitability began to diminish after the first dose, reaching 50 per cent of normal at 55 to 70 per cent of the lethal dose. Atrial arrest occurred at about 80 per cent of the lethal dose when atrial excitability was from 17 to 45 per cent of normal. Shortly thereafter the atria became completely inexcitable.

Ventricular excitability increased slightly (10 to 20 per cent) after the first dose, but after the administration of 60 to 80 per cent of the lethal dose began to diminish rapidly, reaching levels of 50 to 60 per cent of normal shortly before death. Although the first idioventricular beats were recorded at a time when the ventricle was more than normally excitable the frequency of extrasystoles increased leading eventually to multifocal ventricular rhythms and fibrillation, as the excitability diminished below normal levels. The ectopic activity produced by toxic doses of digitals cannot therefore be explained in terms of electrical excitability but rather of increased automatism.

A-V conduction, as expected, was slowed progressively after the first dose until complete block occurred at 55 to 70 per cent of the lethal dose. Severe impairment of A-V conduction was evident before any slowing of intraventricular conduction could be measured. Ventricular conduction from a stimulating to a recording electrode less than 15 mm distant was rarely delayed and often accelerated even in the terminal stage of intoxication. The time interval between near and distant electrodes was not altered until about 70 per cent of the lethal dose had been administered but then increased progressively until death. Since propagation of a forced beat from the point of stimulation to a near electrode must represent chiefly muscular conduction and to a distant

pout chiefly Purkinje conduction, it would appear that digitalis specifically depresses the specialized conducting tissue. Digitalis fibrillation becomes possible when conduction in the Purkinje tissue has been depressed so much that an excitation wave has not yet reached the most distant fibers at the time when a new impulse has begun.

51 ETIOLOGY OF AURICULAR FIBRILLATION AND THE MECHANISM OF ITS PERPETUATION

J. G. SCHLICHTER, M.D., CHICAGO, ILL.
(INTRODUCED BY L. N. KATZ, M.D.)

Observations on man and the dog are presented which relate to the etiology of auricular fibrillation and the mechanism of its perpetuation. Vagal stimulation and anoxia are the main etiologic factors in the initiation and perpetuation of auricular fibrillation.

Vagal stimulation (mechanical and chemical) may induce auricular fibrillation. Acetylcholine injected directly into the blood stream was used in our experiments to produce chemical vagal stimulation. Moderate anoxia reduces the threshold of the auricles to the initiation of fibrillation but does not induce this arrhythmia per se, marked anoxia, on the other hand, increases the threshold to initiating fibrillation.

Anoxia of the auricles was found or produced (1) by interference with or obstruction of its vascular supply, (2) by a decrease in the amount of oxygen carriers, (3) by a decreased oxygen content of the blood due to anoxic anoxemia, and (4) by interference with tissue respiration. The relationship between vagal stimulation and anoxia can be plotted in a graph and on this correlation the cause of the perpetuation of auricular fibrillation can be demonstrated. The clinical implication of these findings and the therapeutic approach to this problem are illustrated and discussed.

52 DICUMAROL AND QUINIDINE IN THE AMBULATORY TREATMENT OF CHRONIC AURICULAR FIBRILLATION

E. V. FEIGIN, M.D. (BY INVITATION), AND S. A. WEISMAN, M.D.
LOS ANGELES, CALIF.

This report consists of a study on thirty-three cases of chronic auricular fibrillation treated from the outpatient department of the Los Angeles County General Hospital.

The purpose of this investigation was to (1) add preventive measures against possible thrombus formation in the auricle and thereby help eliminate the probability of embolic phenomena after restoring a chronic fibrillating heart to normal rhythm, (2) to re-establish normal sinus rhythm, (3) To re-evaluate the difference between the cardiac output in a slow fibrillating heart and that of the heart after it has been restored to normal sinus rhythm.

Material —

Sex Twenty-nine males, four females

Age range 17 to 83 years

Etiology Rheumatoid group, twenty-one cases, arteriosclerotic and hypertension group, twelve cases

Duration of fibrillation Approximately two years

Technique—(1) Patients were first digitalized (2) Circulation time, venous pressure, and vital capacity were then determined (3) Dicumarol was administered until a prothrombin level of between 30 and 20 per cent was obtained (4) Quinidine therapy was then given in daily increasing doses. The maximum amount of quinidine given any patient in a twenty four hour period was 30 grains (5) After normal sinus rhythm was obtained circulation time, venous pressure, and vital capacity were again determined

Results—In eighteen of the thirty three patients 55 per cent normal rhythm was restored. It was also restored in ten patients 48 per cent of the rheumatoid group and eight 67 per cent of the arteriosclerotic and hypertension group

Laboratory findings in the restored group. *Vital capacity* increased on the average of 20 per cent. *Venous pressure* lowered on the average of 60 mm. *Circulation time* either increased on the average of 3 seconds. Calcium gluconate increased on the average of 8 seconds

53 EXPERIMENTAL STUDIES ON THE COMBINED ACTION OF DIGITALIS (CEDILANID) AND QUINIDINE (IN CATS)

S. A. WEISMAN, M.D., LOS ANGELES, CALIF.

The meaning of the term 'combined action' of quinidine and digitalis on the heart, as discussed in the literature perhaps warrants some clarification. It usually refers to the action of these drugs on the heart after they have been given following each other at varying time intervals.

The purpose of this study was to (1) reinvestigate the pharmacologic action of digitalis and quinidine on the heart after giving these drugs in consecutive order at varying time intervals (2) to study the effect of these drugs on the heart after both drugs are administered together and (3) to reinvestigate the effect of quinidine on respiration following the administration of digitalis and the effect on respiration after these drugs are given simultaneously.

Comparative studies were made on the (1) mortality (2) heart rate, (3) blood pressure, (4) electrocardiographic changes (5) respiration.

Results—It was found that there appeared to be less toxic effects on the heart and the respiration after these drugs were administered together than when they were given in consecutive order.

The clinical application of these observations is discussed.

54 PAROXYSMAL TACHYCARDIA LOW NODAL IN ORIGIN BENEFITED BY CARDIAC SYMPATHECTOMY

PAUL A. MEREDITH, M.D. (BY INVITATION) FORD K. HICK, M.D., AND
WESLEY A. GUSTAFSON, M.D. (BY INVITATION) CHICAGO, ILL.

A 35 year old, cyanotic, white female a complete invalid because of incapacitating paroxysms of tachycardia lasting up to fifteen minutes in duration and occurring thirty to forty times per day was admitted to the hospital for study.

General medical history was of cyanosis since birth rheumatic fever at 6 years of age diphtheria at 7 mastoidectomy at 7 at 22 years she had had a cerebrovascular accident with hemiplegia and aphasia which essentially cleared in six months.

The exact nature of the congenital cardiac anomaly was not determined, but it was clinically diagnosed as cor triloculare biatriatum. The laboratory work-up revealed a slight polycythemia (hematocrit, 55 per cent, RBC, 5.5 million) and electrocardiographic evidence that the origin of the impulse of the cardiac stimulus was either low nodal or high in the bundle of His.

The first attack of paroxysmal tachycardia noted by the mother was when the patient was 3½ years of age, and the attacks had progressed from once a month to the present frequency. It was early noted that vomiting caused a cessation of the fast rate and thus and other manipulations were utilized by the patient. Electrocardiographic tracings were taken when the patient would initiate a paroxysm of tachycardia by exertion and then stop the same by pharyngeal stimulation. Cardiac asystole up to 3 seconds in duration followed this conversion of rhythm.

It was surprising that the autonomic nervous system exercised control over cardiac impulse of such low origin. To establish the presence of this control a pharmacologic approach was taken, yielding the following results. Atropine sulfate, given by hypodermic needle, within ten minutes produced a tachycardia which persisted for several hours, quinine sulfate in minimal doses resulted in an increase in frequency and duration of the paroxysms of tachycardia, Prostigmine produced no change, digitoxin in therapeutic and near toxic doses gave a decrease in frequency and duration of the paroxysms, diisopropyl fluorophosphate resulted in decreased frequency and duration of the paroxysms (Di-isopropyl-fluorophosphate destroys cholinesterase which in turn allows enhancement of the vagus through prolonged action of acetylcholine).

In the light of these findings it was felt warranted to remove the cardiac autonomic accelerators (the cardiac sympathetics) in an attempt to stabilize the cardiac rhythm at its slower rate. A two stage bilateral cardiac sympathectomy of stellate ganglion and the first, second, third, fourth, and fifth thoracic nerves was done.

Since surgery the patient has experienced only about five paroxysms of tachycardia per day, lasting only a few seconds.

55 THE EFFECT OF APPREHENSION CAUSED BY THE TECHNICAL PROCEDURES ON CARDIAC OUTPUT

LAWRENCE G. MAY, M.D. (BY INVITATION), ALENE BENNETT, M.D. (BY INVITATION), A. L. LANE, M.D. (BY INVITATION), E. D. FUTCH, M.D. (BY INVITATION), MARY LYNN SCHOOMER, M.D. (BY INVITATION), AND RAYMOND GREGORY, M.D., GALVESTON, TEXAS

In the course of studies of the effect of spinal anesthesia on cardiac output, the variability due to apprehension was so extreme as to make the results of these studies wholly unreliable because initial control values within normal basal range could seldom be obtained. Furthermore the cardiac output varied unpredictably during the course of the procedures. The variations from standard and normal values were always high.

This report is based on a study of cardiac output by the direct Fick method in twenty-four individuals. There were never less than three serial determinations of cardiac output during an experimental period in any patient. In nine patients four consecutive cardiac outputs were done at each experimental period.

It was our belief that high values were due to apprehension. In general, the rate of oxygen consumption bore out this belief. Attempts to use the appearance of the patient, pulse rates, and respiratory rates as criteria for excitement failed to correlate with either our cardiac output results or with the oxygen consumption.

When control values of cardiac output were within normal limits, spinal anesthesia to the first thoracic nerve did not cause decrease in cardiac output. When control cardiac output values were high spinal anesthesia caused them to drop to normal levels. This is probably due to temporary denervation of the heart caused by the high spinal anesthesia.

Our frequent inability to obtain normal cardiac output values for control observations caused us to sedate our patients with Nembutal morphine, and scopolamine prior to and during the observations. The uniformly normal control cardiac outputs which we obtained in twelve patients with such sedation have been so satisfactory as to make us believe that sedation is essential in studies which are directed at determining the effect of certain procedures on cardiac output.

56 THE EFFECTS OF ACUTE HYPOXIA ON THE SENSITIVITY OF THE HEART TO ACETYLCHOLINE

C CALLFAUT MD (BY INVITATION) M I FELDMAN JR MD (BY INVITATION),
S ROBBARD MD (BY INVITATION) AND L A KATZ MD CHICAGO, ILL

This laboratory has recently been engaged in a study of the physiologic responses of the circulation to acute hypoxia. We have shown that during acute severe hypoxia the response of the blood vessels to epinephrine is greatly reduced and that this substance persists in the blood beyond the hypoxic period when relief of hypoxia is quickly introduced. The effect of hypoxia on the action of acetylcholine on the cardiac pacemakers has also been analyzed. In the present study the effect of hypoxia on the sensitivity of the heart to acetylcholine was measured.

In nine dogs catheters were inserted into the left femoral artery and passed under fluoroscopic control into the region of the sinuses of Valsalva. One hundred two injections of acetylcholine were used during hypoxia and the decrease in rhythmicity and conductivity which was produced was recorded electrocardiographically. The threshold dose of acetylcholine injected via the catheter required to produce slowing or block was established during air breathing before and after each hypoxia test. Nitrogen breathing was substituted for air to produce the hypoxia. It was found that the sensitivity of the heart to acetylcholine increased progressively with the continuation of nitrogen breathing, as illustrated in Table I.

TABLE I

DURATION OF HYPOXIA (SEC)	INCREASE IN R-R DISTANCE (SEC)	PRESENCE OF A-V BLOCK
Control	0	0
30	0.3	0
60	0.5	+
100	1.1	+
140	1.7	+
180	2.5	+
220	3.8	+

Relief of hypoxia by reoxygenation resulted in a return of the acetylcholine sensitivity to normal within the next minute or two.

The cardiac slowing and asystole sometimes seen in acute hypoxia may be related to a similar potentiation of acetylcholine action. It is possible that the apparent increase of cardiac sensitivity to acetylcholine is in reality the result of continued presence during hypoxia of endogenous acetylcholine in increasing amounts summing with that injected.

57 THE EFFECT OF CERTAIN SYMPATHOLYTIC AGENTS ON THE CORONARY BLOOD FLOW OF THE DOG

GEORGE V LFROY, M D , L A NALEFSKI, M D (BY INVITATION), AND
HAROLD W CHRISTY, M D (BY INVITATION), CHICAGO, ILL

The effect of tetraethylammonium bromide and Dibenamine on the coronary blood flow of dogs was investigated using a modified Morawitz cannula technique for measuring the coronary sinus outflow. The conditions of administration approximated those used in ordinary clinical practice. With tetraethylammonium bromide there was no influence on the coronary sinus outflow while the drug was being injected. After the intravenous infusion was completed, a small increase of the flow was usually observed. The drug had no effect on the characteristic coronary vasodilator action of adrenalin. Intramuscular injection of tetraethylammonium bromide had no detectable influence on the coronary blood flow over a period of several hours. When Dibenamine was given by venoclysis, no change was seen in the coronary flow during, or for several hours after, administration. With the doses used the peripheral vasoconstrictor action of adrenalin was either reversed or nullified. The typical coronary vasodilator action of adrenalin was not affected by Dibenamine. In dogs that had received Dibenamine, stimulation of the peripheral ends of the cut vagi resulted in a modified response. It is apparent that the action of these sympatholytic agents on the coronary blood flow is distinctly different from their action on the blood flow in the extremities. Since these animals were all normotensive it was not surprising to find that there was only a moderate decrease in systolic blood pressure during the administration of tetraethylammonium bromide and Dibenamine. The fact that these sympatholytic agents which are capable of markedly increasing the blood flow of the limbs did not alter the coronary blood flow is of clinical interest.

58 DIBENAMINE

MAURICE HARDGROVE, M D , AND DANIEL J MENDELSON, M D (BY INVITATION)
MILWAUKEE, WIS

A study was made of the effect of Dibenamine (dibenzyl beta chloroethyl amine) on blood pressure and the peripheral arterial system. Toxic effects were noted. The drug is a tertiary amine and is sympatholytic and adrenergic in action.

Dibenamine was given intravenously to six patients. Five of the patients had essential hypertension and one had normal blood pressure. Skin temperatures were determined on four of the patients after the administration of Dibenamine. The first patient studied received a dose of 25 mg per kilogram and the other five received a dosage of 40 mg per kilogram.

Dibenamine caused a marked orthostatic hypotension lasting from five to twenty-four hours in all six patients. It also caused a rise in the skin temperature of the lower extremities. The maximum rise in temperature occurred within three to five hours after giving the drug and lasted for from five to forty-nine hours. The vasodilator effect upon the skin lasted longer than the effect upon the blood pressure. Toxic reactions consisted of nausea and vomiting in one case and thrombophlebitis in another. Marked vertigo and faintness occurred in all patients on assuming the standing position. These symptoms disappeared upon reclining. Contraction of the pupils occurred in all. Nasal congestion occurred in five, and two patients complained of dryness of the mouth.

59 THE EFFECTS OF DIHYDROERGOCORININE ON THE PERIPHERAL CIRCULATION IN MAN

DANIEL W. HAYES, MD (BY INVITATION) KHALIL G. WAKIM, MD, PH.D.,
 BYARD T. HORTON, MD, AND GUSTAVS A. PETERS, MD (BY INVITATION)
 ROCHESTER, MINN.

The effects of the intravenous administration of dihydroergocorinine (DHEC 180), an ergotonic alkaloid on skin temperatures, blood pressure, heart rate and peripheral blood flow were studied in twenty human volunteers. The action of the drug is chiefly sympatholytic and therefore the drug is considered to be a vasodilator. It was administered to six patients by intravenous infusion in a solution containing 0.5 mg of dihydroergocorinine per 100 cc of physiologic saline solution and to fourteen patients by a single intravenous injection. The total dosage varied from 0.25 to 0.4 mg. Control values for skin temperatures, blood pressure, heart rate, and blood flow were determined before the drug was given, and the observations were again recorded at regular intervals for a period averaging sixty-five minutes after administration of the drug. The blood flow was determined by means of a venous occlusion plethysmograph with a compensating spirometer recorder. Skin temperatures were recorded by means of thermocouples applied to the skin over the forehead, over the right and left deltoid muscles, and over the right and left quadriceps femoris muscles.

Dihydroergocorinine produced an overall average increase in peripheral blood flow of 95 per cent in the upper extremities and 68 per cent in the lower extremities in nineteen of twenty cases. In spite of the increase in blood flow in the extremities, the skin temperatures were slightly decreased even during the maximal increase in blood flow.

The blood pressure fell in the two hypertensive patients after administration of dihydroergocorinine. The decrease of systolic pressure was 58 mm Hg in one case and 30 mm Hg in the other, while the diastolic pressure fell 18 mm Hg in the former and 10 mm Hg in the latter. In normotensive subjects there was no significant change in blood pressure.

The heart rate decreased in every case with an average reduction of 13 beats per minute.

Side reactions were more frequent than had been reported by other investigators even with lower dosage. Nasal congestion, nausea, headache, flushing, an urgency for micturition and vomiting were the side reactions observed.

60 RELATION OF TOBACCO SMOKING TO DISEASES OF THE RESPIRATORY AND CIRCULATORY SYSTEMS

C. A. MILLS, MD, AND MARJORIE MILLS PORTER, MD (BY INVITATION)
 CINCINNATI, OHIO

In order to have a satisfactory picture of normal smoking habits, we made a house-to-house survey in every census tract of the city of Columbus, Ohio, with a verbal questionnaire on individual smoking habits of persons over 20 years of age. About 1,000 persons of each sex and color were interviewed and the results summarized by age groups and city districts (suburban, intermediate and slum). The details of this survey will serve as a useful basis of normal smoking habits in future studies when they are published in detail.

The smoking habits of persons dying of buccal and respiratory tract cancer in Cincinnati and Detroit were compared with those of the Columbus controls and the following differences noted: (1) The incidence of cigar and pipe smok-

ing was very significantly higher among both the buccal and the respiratory tract male cancer victims than among men of corresponding ages in Columbus, while the incidence of nonsmokers was significantly lower than among the proper Columbus controls. Cigarette smoking incidence did not differ significantly from the Columbus standard for either these male or female cancer victims.

With individuals suffering from pulmonary tuberculosis in Dunham Hospital (Cincinnati), the pipe and cigar smoking habits of men were found to be similar to those of the proper Columbus controls, but the incidence of cigarette smoking was significantly higher than normal among both male and female patients. Studies on smoking habits of pneumonia victims are not yet far enough along to report.

Although tobacco smoking has been strongly indicted in various diseases of the circulatory system, adequate detailed and convincing proof has been lacking up to now. To supply proof which could be quantitatively essayed on a mathematical basis, we mailed questionnaires on tobacco smoking habits to the next of kin or informant named on death certificates of all white persons dying in Cincinnati from coronary heart disease during the two years 1946 and 1947. From the returned questionnaires the following findings were obtained: (1) all white victims under 40 years of age were cigarette smokers, (2) the heavy preponderance of cigarette smokers gradually decreased to near the expected normal by the age of 70 years, but by then pipe and cigar smoking was significantly above normal, (3) at all ages the percentage of nonsmokers was very significantly below that found among appropriate Columbus controls.

This survey is being extended to include peptic ulcer and certain other states in which nicotine effects on the autonomic ganglion cells might play a role.

It does seem clear that cigar and pipe smoking is significantly related to cancer of the air passages and lungs, while cigarette smoking is significantly related to infectious diseases of the respiratory tract. Cigarette smoking below 65 years of age and pipe or cigar smoking above that age are significantly related to fatal attacks of coronary heart disease.

61 FACTORS INFLUENCING THE T WAVE OF THE ELECTROCARDIOGRAM, AN EXPERIMENTAL STUDY EMPLOYING INTRACAVITARY AND EPICARDIAL LEADS

I EFFECTS OF HEATING AND COOLING OF SUBEPICARDIAL AND SUBENDOCARDIAL LAMINA

HERMAN K. HELLERSTEIN, M.D., AND IRVING M. LIEBOW, M.D., CLEVELAND, OHIO

(INTRODUCED BY HAROLD FEHL, M.D.)

Only recently has the question been raised as to the contribution of depolarization and repolarization of the subendocardial lamina to the genesis of the electrocardiogram. The employment of intracardiac catheter electrodes has facilitated the study of the electrical influence of the myocardium. In the present study this technique was employed to investigate the genesis of electrical events established by changes in the rate and direction of repolarization of subepicardial and subendocardial lamina. These changes were produced by heating and cooling the epicardium and the endocardium. Intra- and extracardiac (epicardial) exploring unipolar electrodes were used. The method of changing the temperature of the subendocardial surface relative to that of the epicardium consisted of introducing physiologic saline at various temperatures through in-dwelling intracavitary catheter electrodes. Epicardial thermal changes were

produced by local application of cold and hot saline soaked pads and ice cubes of various sizes. The effects were immediate with rapid recovery occurring in ten seconds to two minutes.

Negative T waves occurred where the exploring electrode immediately subtended areas which had relatively or absolutely retarded repolarization. Positive T waves occurred where the exploring electrode faced areas which had relatively or absolutely accelerated repolarization.

It was found that negative T waves occurred

A In the cavity (1) when the endocardium was cooled (2) when the endocardium was not altered, but the epicardium was heated

B On the epicardium (1) when the epicardium immediately under the electrode was cooled, (2) when the endocardium subjacent to the epicardial exploring electrode was heated (3) when the endocardium of the opposite wall was cooled

Positive T waves occurred

A In the cavity (1) when the endocardium was heated, (2) when the epicardium was cooled

B On the epicardium (1) when the subjacent epicardium was heated, (2) when the subjacent endocardium was cooled

Direct evidence has been obtained that changes in the electrical state of the subendocardial muscular lamina modify the form of the electrocardiogram. Changes in the T wave can be produced by changing the rate and order of endocardial epicardial laminar repolarization.

The relation of our results to the modern concept of altered repolarization in an extensive conducting medium is discussed. The spatial relation of the exploring electrode to a theoretical surface at the junction of the normal and altered areas is used to account adequately for the findings.

The practical value of these observations is discussed.

The present results confirm and extend previous observations on the contribution of the subendocardial myocardium to the electrocardiogram.

62 A DIRECT WRITING OSSIOLOGRAPH FOR RECORDING DATA OBTAINED BY THE METHOD OF CARDIAC CATHETERIZATION

ROY W. SCOTT, M.D., AND HENRY A. ZIMMERMAN, M.D. (BY INVITATION)
CLEVELAND, OHIO

With the cooperation of the Brush Development Company of Cleveland we have adapted their direct writing six channel Ossilograph for recording simultaneously such data as the electrocardiogram, femoral arterial pressure, intracardiac or pulmonary arterial pressure, the respiratory cycle time in seconds, and the Balistocardiogram. By using strain amplifiers, pressure transmitters, and strain gauges we have found that this system records accurately variations in blood pressure as checked with the Hamilton manometer. Furthermore the system has certain advantages such as linearity of range scale, mobility, and direct visualization of phenomena being recorded and it is simple to calibrate. Data as recorded by the Ossilograph and derived from observations on patients with heart disease are presented in a series of lantern slides.

63 A COMPARATIVE EVALUATION OF EXTREMITY AND PRECORDIAL LEADS IN THE DIAGNOSIS OF ACUTE MYOCARDIAL INFARCTION

IRWIN R. CALLEN, M.D., AND JACK W. FISCHER, M.D., CHICAGO, ILL.

(INTRODUCED BY EDMUND F. FOLFL, M.D.)

There has been a great deal of controversy concerning the relative merits of standard leads I, II, and III versus extremity potentials aV_R , aV_L , and aV_F . In addition the decision whether to use a precordial position with CF, CR, or V as the indifferent electrode has not been decided. Our purpose was to evaluate and compare these leads in recent acute myocardial infarction.

Fifty patients were studied, of whom twenty-five were shown by serial electrocardiographic, clinical, and autopsy data to have had an acute myocardial infarction. Of these twenty-five patients, seven showed equal diagnostic findings in standard leads, extremity potential leads, and precordial leads. Six had anterior involvement and one posterior. There were five in whom the precordial leads showed the most significant findings. The extremity leads I, II, and III and aV_R , aV_L , and aV_F were not normal but showed no acute involvement as manifested by S-T segment elevation or T-wave inversion. In five the extremity potentials aV_R , aV_L , and aV_F were more helpful in making a diagnosis than were the standard leads. In these the precordial leads were very useful also. Four patients with posterior infarctions showed the best changes in the extremity leads, precordial leads not being of much aid. Four others with posterior involvement were definitely aided by precordial leads.

The second study concerning the use of the left foot, the right arm, or the central terminal as the indifferent electrode position did not reveal significant differences. The voltages were not the same, but for clinical purposes they so closely resembled one another that we felt one indifferent electrode position to be as useful as another. When an S-T segment was elevated or a T wave inverted or a deep Q wave present in CF_4 , for example, it was similarly altered in CR_4 and V_4 .

In conclusion the extremity potentials aV_R , aV_L , and aV_F show diagnostic changes more frequently than the standard leads I, II, and III. No significant clinical differences were seen between CF, CR, or V precordial leads in the diagnosis of acute myocardial infarction.

64 THE ELECTROCARDIOGRAPHIC RESPONSE TO THE ANOXEMIA TEST IN PATIENTS WITH HYPERTHYROIDISM

IRWIN R. CALLEN, M.D. (BY INVITATION), AND ROBERT W. KEETON, M.D.
CHICAGO, ILL.

Observations of an anoxemia test that had been performed on a patient taking thyroid extract revealed a positive test. The test became normal on discontinuing thyroid. This led to the study of nine patients with clinical hyperthyroidism. All nine patients were selected carefully so that the symptoms were of recent duration, the basal metabolic rates on repeated tests were over 30 per cent, the age was under 40 years, and repeated examination revealed no evidence of cardiac disease.

It was then presumed that we were dealing with individuals whose hearts were normal except for any influence the hyperthyroidism might have had.

In all nine patients positive tests were observed. The S T segments became depressed below 1 mm and T wave inversion especially in Leads I II, CF₁ and V were seen. As the hyperthyroidism was controlled by medical management propylthiouracil or surgery, the response to the anoxemia test was not as dramatic. Further studies are in progress at this time.

This test with the production of anoxemia has shown objectively the damaging effect of the hyperthyroidism. By implication one might anticipate that patients with normal thyroid glands taking thyroid extract for purposes of reduction would show similar changes.

65 ELECTROCARDIOGRAPHIC CHANGES FOLLOWING MEALS IN PATIENTS WITH ANGINA PECTORIS

BERNARD BERMAN, M.D., CINCINNATI, OHIO

(INTRODUCED BY JOHNSON McCLELLAN, M.D.)

Standard mixed meals, consisting of 90 grams carbohydrate, 40 grams protein and 40 grams fat were given to thirty-two patients with angina pectoris. Electrocardiograms were taken on all patients before meals and thirty minutes following the meal. In some cases electrocardiograms were also taken sixty minutes and ninety minutes following meals. Warm food and warm liquids were used in each meal. In approximately 25 per cent of the patients there occurred a $\frac{1}{2}$ to $\frac{1}{4}$ mm depression of the S T segment and development of or increase in existing concavity of the S T segment. In patients showing this S T change following meals, repeat electrocardiograms showed these findings to be consistent. Fourteen normal controls in the same age group exhibited no similar change.

The effect of meals on the electrocardiogram in these normal controls was similar to that reported by Simonson, Alexander, Henschel and Keys in normal individuals. These changes consisted of the following: a significant increase in heart rate, decrease in Q T interval, decrease in amplitude of the T wave, increase in QRS amplitude and shift of the electrical axis toward the left. The patients with angina pectoris exhibited these changes also.

The electrocardiogram changes induced by the ingestion of food in the anginal patient suggests the possibility of employing this or similar methods as an additional aid in detecting coronary insufficiency.

66 CIRCULATION TIMES FOR ANGIOCARDIOGRAPHY

GEORGE C. SUTTON, M.D., GEORGE E. WENDEL, M.D., HARRY E. GRANT, M.D., AND
EDWARD G. WARRICK, M.D., CHICAGO, ILL.

(INTRODUCED BY DON C. SUTTON, M.D.)

The diagnostic justification for the performance of angiocardio-graphy frequently depends upon obtaining a satisfactory levoangiocardio-graph. This has been difficult to do when using the method of Robb and Steinberg because of difficulty in determining in advance when the contrast media will fill the left heart and aorta. Previous methods of determining circulation times prior to angiocardio-graphy have not been totally satisfactory. Experiments in circulation time conducted by our group confirmed the work of others who had noted that increasing the volume injected decreased the circulation time. In a

group of twenty adults, none of whom had valvular cardiac lesions, increasing the volume of saline diluent from 5 to 50 ml decreased the ether aim to pulmonary capillary circulation time by a mean of 1.3 seconds. A similar increase in volume decreased the sodium cyanide aim to carotid sinus circulation time by a mean of 6.3 seconds. The increased volume of material rapidly injected into the aim vein accelerated the circulation time to the right heart and *through* the lungs and left heart as well. Angiocardiograms timed on the basis of circulation times determined by the use of quantities of material equal to the contrast media used (50 ml in this series), and injected in a manner identical to the media, produced satisfactory levoangiocardigrams.

67 A COMPARATIVE STUDY OF PERIPHERAL AND DIRECT INTRACARDIAC ANGIOCARDIOGRAPHY

GEORGE C. SUTTON, M.D., GEORGE E. WENDEL, M.D., AND
HARRY E. GRANT, M.D., CHICAGO, ILL.

(INTRODUCED BY DON C. SUTTON, M.D.)

Two methods are available for the performance of angiocardiography. The first method, utilizing the injection of the contrast media into a peripheral aim vein, fails to provide satisfactory visualization in a number of patients. This occurs most frequently in adults who possess thick, muscular thoracic walls or dense mediastinal or lung lesions which lessen the contrast of the dye filled structures. Direct intracardiac injection of the contrast media by means of a catheter introduced into the jugular vein in the neck and advanced to the right auricle is the second method. A comparative study of these two procedures has been made by the group working in Peble Laboratory.

68 THE APPEARANCE OF NORMOBLASTS IN THE PERIPHERAL BLOOD IN PATIENTS WITH PULMONARY EMBOLISM

M. C. F. LINDERT, M.D., AND HOWARD L. CORRELL, M.D., MILWAUKEE, WIS.

(INTRODUCED BY MAURICE HARDGROVE, M.D.)

Greater attention is being directed toward the study of the peripheral blood in cardiac failure and associated conditions. The quantitative changes, including the cellular elements, have been observed and reported. References to the qualitative changes of the cellular elements are extremely infrequent. During the past two years we have carefully studied the peripheral blood of all cases of pulmonary embolism that have come to our attention. We are reporting six cases of pulmonary embolism or thrombosis, with resultant right heart failure and the appearance of normoblasts in the peripheral blood stream. Other less noteworthy qualitative changes were observed, such as the findings of reticulocytes and polychromasia. All cases were autopsied, three of which showed extramedullary hematopoiesis. The explanation for the outpouring of normoblasts is not known. Acute severe anoxia would seem to be the most plausible etiologic factor. However, the anoxia produced by sudden altitude changes has not been reported to release normoblasts to the peripheral blood. In view of this, it is felt that other factors must play a role. Some of the additional factors postulated include tissue destruction and hemolysis.

(To be concluded in the December issue)

PARENTERAL NUTRITION

VII METABOLIC STUDIES ON PUPPIES INFUSED WITH FAT EMULSIONS

GEORGE V. MANLY, M.D., ROBERT P. GRYER, PH.D., DONALD M. WATKIN, M.D.
RICHARD L. SMYTHE, A.B., DSAM CHWEN DJU, PH.D., NORMAN
ZAMCHECK, M.D. AND FREDERICK J. STARR, M.D.
BOSTON, MASS.

THE preparation of fat emulsions with high caloric concentrations for parenteral supplementation or replacement of oral feeding has been studied intermittently by various workers for over fifty years.¹⁻⁴ Reports have indicated varying conclusions as to the practicability of preparing an emulsion of fat that can be given intravenously for nutritional purposes. Work done in this laboratory over the past six years has shown that fat emulsions suitable for intravenous administration can be prepared and that the calories in such preparations are available for energy requirements when the emulsions are given intravenously.²⁰

The experiments described in this paper were undertaken in an effort to study the effect of intravenous fat emulsions upon growth, nitrogen balance, and selected biochemical and hematologic functions. Two litters of puppies were used to determine (1) whether young and rapidly growing animals, with a consequently high caloric requirement, can utilize an emulsion of fat given intravenously (2) whether daily infusion in large amounts (15 to 100 Gm. of fat per kilogram of body weight) of the emulsion now used in this laboratory²⁰ will lead to either histologic, hematologic or metabolic injury.

EXPERIMENTAL

The puppies were housed in an air conditioned room in individual metabolism cages permitting accurate collection of urine and feces. They were weighed daily. Nitrogen balance studies were conducted on a three-day interval scheme. The animals were maintained three days on a new regime and the nitrogen intake and output were then measured for each of three consecutive days and the balances were computed for each dog. Nitrogen determinations on diet and excreta were done by the macro Kjeldahl method.

Hematologic studies were done on blood collected in a dry syringe from a foreleg vein and transferred to a tube containing balanced oxalate. Hemoglobin determinations were done by a direct photometric method.²¹ During infusion periods blood was drawn for hematologic and chemical studies just before the start of an infusion; this was usually twenty-four hours after the last infusion.

This research was supported in part by grants in aid from the Williams and Waterman Fund of Research Corporation, New York, N. Y., the National Dairy Council, Chicago, Ill., the Upjohn Company, Kalamazoo, Mich., the Nutrition Foundation, Inc., New York, N. Y., and the Milbank Memorial Fund, New York, N. Y.

Received for publication Aug. 17, 1948.

Emulsion No. 35 composition in grams: coconut oil 300, phosphatide fraction BF 30, dextrose 35, water 634; for details of preparation see reference 5.

Total serum protein and serum albumin were determined by the method of Howe, serum nonprotein nitrogen by the nesslerization procedure of Koch and McMeekin,⁸ and serum bilirubin by the diazotization procedure of Malloy and Evelyn.⁹ Serum total and free cholesterol determinations were done by the method of Schoenheimer and Sjerrv.¹⁰

Bromsulfalein excretion was determined by the method previously described by Mc Kibbin¹¹ and plasma prothrombin by the method of Link.¹² Plasma volumes were determined by the method of Hopper and co workers¹³ and red blood cell fragility by the method of Wintrobe¹⁴ or Parpart.¹⁵ Fecal lipids were determined as follows. Collections of the twenty four hour feces for each dog were mixed in a Waring blender with the additions of 95 per cent ethyl alcohol and concentrated hydrochloric acid until acid to Congo red. An aliquot of the mixture was dried in vacuo and extracted with dry chloroform for twenty four hours in a Soxhlet extractor. The chloroform was then removed in vacuo, the residual fat taken up in low boiling (40 to 60° C) petroleum ether and filtered into tared beakers. The ether was removed and the chloroform extractable, petroleum ether soluble lipid determined by weighing

Fig 1—A photograph of the apparatus used for infusion of animals

Infusions of fat emulsion were carried out by placing the animal in an adjustable animal box in an upright position. A foreleg was secured with adhesive tape and after preparing the area for injection, the needle (No 20 or No 22) attached to the infusion set was inserted into a vein on the dorsum of the leg. When the needle had been taped securely in place the infusion could run for several hours without discomfort to the animal. For accurate measurement of infusion rates we found it advantageous to use an infusion set consisting of a graduated cylinder as a reservoir, a Murphy drip bulb, and a closed system with positive air pressure maintained by an attached blood pressure cuff and aneroid manometer (Fig 1).

The composition of the various diets fed the puppies in these studies is shown in Table I

TABLE I COMPOSITION OF DIETS USED FOR EXPERIMENTS I AND II

J Biol Chem 158:4:2 1941

†Manufacturer's analysis

Experiment 1—A litter of eight Labrador retriever puppies reared in this laboratory was weaned at 6 weeks of age and during two weeks were gradually transferred to diet D1. The animals were fed *ad libitum* the daily food intake was measured, and nitrogen balances were determined at intervals.

After an initial control period four puppies (Nos. 90, 906, 907 and 909) were started on daily infusions of a 30 per cent coconut oil emulsion stabilized with a 1 per cent phosphatide preparation—Emulsion No. 30⁵. Two pups Nos. 904 and 908, were kept as control animals and fed ration D1 *ad libitum*.

The initial infusions were given initially at a rate of 2 to 4 ml per minute and led to two immediate toxic reactions. On the first day of infusions the animals showed evidence of vasomotor collapse with pale mucous membranes and sometimes with drowsiness and defecation. This reaction occurred after no more than 25 ml of the emulsion had been given. After five to ten minutes with the infusions continuing at the initial rate the animals recovered. The reaction did not reoccur on successive days. The second complication of immediate importance was the occurrence of vomiting and anorexia. Vomiting appeared either as a result of rapid infusion or after long continued infusion at a slow rate. Since appetite is determined in part by caloric requirement the infusion of such a large amount of fat (10 Gm of fat per kilogram of body weight) to supply calories would be expected to decrease the oral intake of food to the point of serious limitation of protein, vitamins and minerals. These limitations would in turn aggravate the anorexia and if continued for any time would give rise to serious deficiency complications. When the limitation of oral intake became apparent (after five to seven days) the infusions were stopped for five days and the animals including the two control pups, were transferred to a diet of Games Dog Meal to allow them to regain nutritional equilibrium. Infusions in the experimental animals were commenced again at a rate of 3 to 5 ml per minute but in a total quantity to supply only 15 Gm of fat per kilogram of body weight per day. This was well tolerated. After six days the quantity of emulsion infused was increased to 3 Gm of fat per kilogram. At this level of infusion growth was good and the animals were in positive nitrogen balance while receiving approximately 20 per cent of their caloric requirement as intravenous fat. Figs. 2, 3, 4, and 5 show the data on oral food consumption, infusion of fat, growth, hematologic data, and nitrogen balance obtained on these four puppies. The hematologic data reveal a moderate but significant fall in hemoglobin, red blood cell count

Fig 2—Data obtained from Dog No 905 Experiment 1—infusion of 30 per cent fat emulsion.

and hematocrit. Similar blood changes have been reported from this laboratory by Collins and co-workers¹⁶. It is of interest to note that the anemia produced is self-limited even though infusions continue. The data presented on Pup No 909 in Fig 5 particularly emphasizes this point.

The puppies received 3 Gm of fat per kilogram of body weight per day for six days and then the amount of infused fat was increased to 5 Gm of fat per kilogram. At this higher level the results obtained were not so uniform. Puppies 905 (Fig 2), 906 (Fig 3), and 907 (Fig 4) grew well and remained in positive nitrogen balance, but Puppy 909 (Fig 5) grew poorly and was for a time in negative nitrogen balance. After twenty-one days on this infusion level of 5 Gm of fat per kilogram of body weight, Pup 909 was

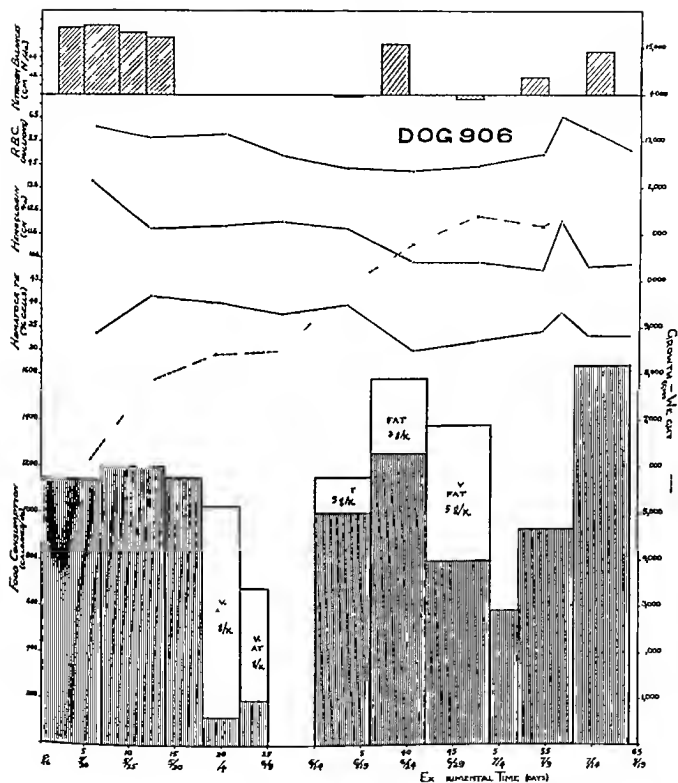

Fig 3—Data obtained from Dog No 906 Experiment 1—infusion of 30 per cent fat emulsion

again given 10 Gm of fat per kilogram per day and continued on this regime for an additional twenty four days with the object of determining the effect of continued large infusions of fat. At this extremely high level of fat infusion the blood lipid level remained high even twenty four hours after the last infusion indicating that the infusions were surpassing the utilization and storage rates. There was occasional vomiting during or immediately after the infusions. Oral intake of food remained essentially constant for the first two weeks following this high level of fat and then progressively diminished. It will be noted that there was a steady gain of weight with an increasingly positive nitrogen balance, until the seventy fifth day of the experiment. After

Fig 4—Data obtained from Dog No 907 Experiment 1—infusion of 30 per cent fat emulsion

this time, the oral intake fell to inadequate levels, the animal became thin and gaunt and died on the ninety-first experimental day. Over the course of the experiment, this animal had received 3,030 Gm of fat by vein. The terminal rise in blood values was probably due to dehydration and hemoconcentration. The precise cause of this dog's death is not known, though the anorexia and inadequate intake of essential nutrients were no doubt important factors. The loss of fat tolerance as indicated by progressive abnormality of tolerance curves may be of significance.

The two control pups (Nos 904 and 908) which had been maintained on a diet of Games Dog Meal grew well, showed a normal blood picture, and except for occasional respiratory infections, appeared in good health.

FIG. 9.—Data obtained from Dog No. 909. Experiment 1—Infusion of 30 per cent fat emulsion

Pathology of Animals in Experiment 1 Table II indicates the relationship of the infusions to the time of autopsy of this group of animals. At post mortem the animals in Experiment 1 showed no gross changes. Microscopic examination of stained sections revealed that the lungs of animals 905 and 907,

TABLE II SUMMARY OF FAT INFUSIONS IN EXPERIMENT 1

DOG	DAYS INFUSED	TOTAL FAT INFUSED (GM)	DAYS AFTER LAST INFUSION ANIMAL SACRIFICED	COMMENT
904	0	0	---	Control animal
908	0	0	---	Control animal
907	22	647	18	Tolerance good
906	26	1,225	110	Tolerance good
905	33	1,466	20	Tolerance good
909	63	3,030	5 hr	Animal died

infused for thirty-three and twenty-two days respectively, contained occasional accumulations of multinucleated giant cells. These were graded 1+ according to the criteria previously outlined.⁵ No granulomatous lesions were found. Fat stains of the liver were not remarkable. The bone marrow showed a moderate degree of hyperplasia. The remaining organs were normal. Animal 909 showed evidence of terminal pneumonia with peribronchial infiltration of inflammatory cells, but neither granulomatous nor giant cell-containing lesions were found. The control animal (No. 904) sacrificed at this time showed similar evidence of pulmonary infection suggesting a viral disease. Infusion animal No. 906 was not sacrificed until one hundred and ten days after the last infusion. The remaining control pup (No. 908) was sacrificed at that time. Neither animal showed any evidence of histologic changes.

Experiment 2—With the experience of the preceding study a second experiment was designed to accomplish two purposes: (1) to avoid the immediate toxic reactions and anorexia complicating the first experiment by more judicious adjustment of the rate and amount of infusion and composition of the diet, (2) to study several metabolic functions of the animals in order to determine the effects of both the complete emulsion (Emulsion 35⁵) and the phosphatide emulsifier BF2⁵ alone.

A litter of eight mongrel puppies was placed on diet D2 (Table I) at 16 weeks of age. The animal procedures and nitrogen collections were carried out as described for the preceding experiment. In addition to hematologic studies, the following determinations were made at regular intervals: serum total protein and albumin, serum total and free cholesterol, serum nonprotein nitrogen, plasma volume, bromsulfalein clearance, serum bilirubin, and plasma prothrombin concentration.

The eight animals were divided into four groups of two animals each as indicated in Table III. Animals I and II were infused with a 30 per cent coconut oil emulsion stabilized with 3 per cent of a phosphatide fraction (Emulsion 35). Animals III and VI, with an emulsion of 3 per cent phosphatide fraction BF2⁵ without added fat, animals IV and V were not infused but were pair-fed with animals I and II respectively. Animals VII and VIII served

as controls, were not infused, and were fed diet D2 ad libitum. The infusions were given at a rate of 3 to 5 ml per minute and animals I and II which received the fat emulsion obtained a total of 2 Gm of fat per kilogram of body weight per day from this source for the first two days, 3 Gm of fat per kilogram for the next seventeen days, and 5 Gm of fat per kilogram for the last twelve days.

TABLE III SUMMARY OF FAT INFUSIONS IN EXPERIMENT 3

DOG	INFUSION	ORAL FOOD	INFUSION TIME (DAYS)	TOTAL COCONUT OIL INFUSED (GM)	TOTAL PHOSPHO LIPID BF2 (GM)	TIME AFTER LAST INFUSION SACRIFICED (DAYS)
I	30% fat emulsion	Diet D2 ad libitum	31	1.066	1.1	16
II	30% fat emulsion	Diet D2 ad libitum	31	1.386	1.39	16
III	3% BF2	Diet D2 ad libitum	31	0	106	16
VI	3% BF2	Diet D2 ad libitum	31	0	142	16
IV	0	Pair fed with Dog I	4	.292	.29	9
V	0	Pair fed with Dog II	4	.92	.9	5 hr
VII	0	Ad libitum control	0	0	0	0
VIII	0	Ad libitum control	0	0	0	0

The course of this experiment is charted in Figs 6, 7, 8 and 9. Fig 6 presents the data obtained on animals I and II which were infused with the 30 per cent of fat emulsion. The data emphasize again adjustment of appetite and oral food intake to maintain a constant total caloric intake. These two puppies grew well if not better than the ad libitum fed control animals (animals VII and VIII, Fig 9) although they obtained 25 to 30 per cent of their total calories from intravenous fat. Fig 7 shows the data on animals III and VI and it is seen that the phosphatide material BF2 alone had little if any, effect upon appetite or growth.

Nitrogen assimilation was comparable in the infused dogs with that of the control, noninfused animals. In sharp contrast Dogs IV and V, pair fed with Dogs I and II, were barely able to maintain their body weight and nitrogen equilibrium (Fig 8). They were, of course, receiving fewer calories to the extent of the calories furnished by the parenteral fat to Puppies I and II. The growth curves of each pair of animals in this experiment have been averaged and are all presented for comparison in Fig 10.

Since Puppies IV and V were behind in growth it was decided to give them large infusions of fat to see whether there would be a prompt gain in weight. Accordingly, on the fifty second day of the experiment a series of four infusions of a 30 per cent fat emulsion amounting to 10 Gm of fat per kilogram of body weight were given. Unfortunately this emulsion was prepared by a different procedure and proved to be unstable in vivo. As Figs 8 and 11 indicate it was immediately toxic. Because of the toxic reactions of this poor batch of emulsion animals IV and V are excluded from the discussion of post mortem changes.

no infusion.

GROWTH CURVES OF PUPPIES

Fig 10—Growth curves of all animals in Experiment 2

Hematologic studies revealed a small but significant and self-limiting fall of hemoglobin, hematocrit, and red blood count during the first two weeks of the infusion period. This change was of the same magnitude in the animals receiving the phosphatide BF2 alone as in those receiving the fat emulsion. Serum bilirubin determinations during this period did not reveal evidences of increased blood destruction.

Determinations of red blood cell fragility revealed consistently decreased resistance of the infused animals' blood cells to hypotonic saline, this seemed to be caused by the phosphatide emulsifier rather than by the fat itself since the effect was no greater in the dogs receiving the coconut oil emulsion than in those receiving only the phosphatide. The mechanism of this effect has not been established.

Neither the serum protein concentration nor the total circulating serum protein calculated from plasma volumes was significantly altered. Serum albumin concentration and total circulating serum albumin were not significantly changed. The serum nonprotein nitrogen remained within normal limits.

An interesting and perhaps significant finding detected in the infused animals was a striking increase in the proportion of free serum cholesterol. This increase became significant two weeks after the start of the infusions and it was more marked in the animals receiving only the phosphatide stabilizer. One week after cessation of infusion the ratio of free to total cholesterol had returned to normal. The serum cholesterol changes in Puppies

CHOLESTEROL VARIATIONS IN DOGS AFTER INFUSION OF LIPIDS

Fig 11—Cholesterol variations in all dog in Experiment. Dogs I and II infused with 30 per cent fat emulsion. Dogs III and VI infused with phosphatide stabilizer without added fat. Dogs IV, V, VII and VIII not infused.

IV and V which received four infusions of a poor batch of emulsion beginning on the fifty second day of the experiment are of interest. A week after the last of these infusions the ratio of free to total cholesterol had risen from a normal range of 0.25-0.33, to 0.46. There was a small increase of total serum cholesterol, and there was a prompt increase of bromsulfalein retention. Fig 11 is a graphic representation of the cholesterol data.

Except in Dogs IV and V after they had received the unstable and toxic emulsion, the liver function, as determined by serum bromsulfalein tests revealed no abnormality to correlate with the serum cholesterol. Plasma prothrombin determinations at the close of the infusion period were normal.

The possibility of an increased fecal excretion of fat by the animals receiving fat emulsions was considered and hence twenty four hour stool specimens were analyzed for total lipids. Table IV illustrates the fecal lipid excretion of the animals for an average period. It is seen that fecal lipids are not increased during the infusion of fat. Urinary studies showed that the urine contained insignificant amounts of lipids.

TABLE IV FECAL LIPID EXCRETION DURING FAT INFUSION IN EXPERIMENT 2

DOG	INFUSION	AVERAGE 24 HOUR FECAL LIPID EXCRETION (GM)
I	Fat, 5 Gm/kg	3.53
II	Fat, 5 Gm/kg	
III	Phosphatide, 0.5 Gm/kg	2.71
VI	Phosphatide, 0.5 Gm/kg	
IV	0	1.65
V	0	
VII	0	4.06
VIII	0	

Pathology of Animals in Experiment 2 The animals in Experiment 2 were sacrificed for post-mortem study as indicated in Table III. The gross appearance of the organs and tissues was normal. Table V indicates the organ weights at autopsy. These were not unusual except for the spleens of animals III and VI which were significantly enlarged. Sections of the tissues were preserved in 10 per cent formalin for histologic study and other sections of the lungs, heart muscle, liver, spleen, pancreas, and kidneys were removed and immediately frozen at -20°C and stored at this temperature for lipid analyses.

TABLE V ORGAN WEIGHTS OF ANIMALS IN EXPERIMENT 2 AT AUTOPSY

DOG	MATERIAL INFUSED	INFUSION DURATION (DAYS)	INTERVAL AFTER INFUSION BEFORE AUTOPSY (DAYS)	LUNGS (GM)		HEART (GM)	LIVER (GM)	SPLEEN (GM)	PANCREAS (GM)	KIDNEYS (GM)	
				L	R					L	R
I	Fat emulsion	31	16	40	65	95	530	75	25	30	30
II	Fat emulsion	31	16	45	65	115	560	65	29	37	37
III	Phosphatide	31	16	18	45	65	380	80	20	25	25
	fraction BF2										
VI	Phosphatide	31	16	42	62	100	500	85	36	42	37
	fraction BF2										
VII	0	0	0	35	52	97	385	37	32	33	33
VIII	0	0	0	37	54	78	371	24	23	26	28

Microscopic examination of sections of the lungs of the infused animals showed them to be normal. Sections stained with sudan III revealed no unusual fat deposition. Sections of heart muscle were normal as were the sections of aorta. No intimal lipid deposits could be demonstrated. The thymus and lymph nodes were not unusual and the adrenals appeared normal.

The spleens and livers of all infused animals showed an increase in pigment which appeared as brownish-black granules in the sinusoids and Kupffer cells. This pigment was more prominent in animals III and IV which had received the phosphatide stabilizer alone than in the animals receiving the emulsion of fat. All the infused animals were found to have occasional small focal accumulations of mononuclear cells in the liver, these consisted of four to ten cells negative for lipid by sudan stain. There were no multinucleated giant cells. There was no evidence of abnormal fat deposition in the liver.

The kidneys were found to be normal in all animals. The marrow unfortunately, was not suitably fixed for adequate study.

The histologic changes following the infusions were thus of two types—both minimal. First infused animals showed an increase of pigment deposition in the phagocytic cells of the liver and sinusoids of the spleen and second seated small round cell infiltrations were found in the liver.

Lipid Analysis of Organs From Animals in Experiment 2 The frozen tissues were thawed and two portions of each organ were dissected free of adherent tissues. One portion was weighed wet dried in an oven at 105° C for

forty-eight hours to a constant weight, and the percentage dry matter calculated. Another similar portion was weighed and ground with three times its weight of anhydrous sodium sulfate until a fine, pink powder was obtained. This material was air-dried, transferred quantitatively to Soxhlet thimbles, and extracted twenty-four hours with redistilled, dry chloroform. The chloroform was removed and the residue dried in vacuo. The residual lipids were taken up in low-boiling petroleum ether and filtered through fat free paper into a 100 ml volumetric flask. The contents were then made to volume with ether and aliquots taken for gravimetric determination of total lipids. Additional aliquots were taken for determination of total and free cholesterol by the Schoenheimer-Sperry method¹⁰, of phospholipids and free fatty acids by the titrimetric method of Man and Gildea¹⁷, and for determination of total lipid phosphorus using the method of Youngberg¹⁸. The per cent of total lipids present as neutral fat was then calculated by difference. These data are summarized in Table VI. It is seen that the total lipid content of the six organs examined from each animal was not significantly different in the four infused animals or in the noninfused animals. The values obtained are similar to those reported by other workers¹⁹ for normal dogs and confirm the histologic evidence which revealed no abnormal lipid deposits in the tissues.

The livers of the four infused animals showed an increase of total cholesterol over the controls. This increase is associated with an increase of the ratio between the free to total cholesterol components. This was the only tissue which showed an abnormality of cholesterol content. The changes were of the type already described in the plasma, the total cholesterol content is increased with a marked increase in the ratio of free to ester cholesterol. As noted, the plasma cholesterol ratios had returned to normal sixteen days after the last infusion.

DISCUSSION

The data obtained in these studies give additional support to findings from this laboratory that a properly prepared emulsion of triglycerides given intravenously is utilized for energy requirements. The use of litters of growing puppies has proved to be a sensitive indicator of these functions. It has also been shown that proper selection of phosphatide stabilizers and careful preparation will give a stable emulsion of fat which can readily be infused in amounts up to 5 Gm of fat per kilogram of body weight per day. This amount of fat represents 20 to 30 per cent of the caloric requirement of an actively growing animal. Microscopic and chemical examination of the tissues of infused animals revealed minimal cellular reaction in the livers which is transient and after a few weeks leaves no apparent anatomical damage.

Although two of the puppies in Experiment 1 showed minimal evidence of histologic changes which may be attributed to the emulsions infused when sacrificed two to three weeks after the termination of the infusions, these changes were of questionable significance. Certainly there was no evidence of irreversible tissue damage as the result of continued infusions of large amounts of emulsion.

Animal 906 was found to be free of lesions four to five months later and Dog 909 which had received over 3 kg of fat intravenously in a period of sixty three days showed no histologic evidence of damage when examined at the end of the infusion period. Furthermore histologic data corroborate metabolic data indicating that the infused fat was disposed of in an orderly fashion and was apparently converted to energy and growth requirements. Even when as much as 10 Gm of fat per kilo, gram per day was infused there was no evidence that fat was deposited in the liver or other organs to the detriment of function at these sites. Chemical analysis revealed a disturbance of cholesterol metabolism leading to an increase of free cholesterol with a concomitant reduction of ester cholesterol in the plasma. A similar change of the cholesterol distribution and content was found in the livers of all infused animals sixteen days after the last infusion. There was no evidence of excessive deposition of lipids in the liver or other visceral organs. Liver function tests did not indicate injury to this organ other than the disturbance of cholesterol metabolism. A moderate anemia was consistently observed in the infused animals but it seemed to be self limited and improvement was prompt with cessation of the infusions. Since the anemia was of equal degree in the animals receiving only the phosphatide stabilizer it appeared not to be due directly to the fat. In many respects this anemia resembled the anemia of infection.

The relationship of appetite to the amount of infused fat suggests that the oral intake is determined in part by the total caloric requirement. The parenteral use of fat emulsions of high caloric concentration allows a promising approach to the problem of supplying adequate calories in a small fluid volume for individuals who are in caloric deficit and unable to take sufficient calories by mouth. However, if calories provided by vein are sufficient to reduce markedly the appetite and hence oral intake one may soon encounter or aggravate complications related to an inadequate intake of protein vitamins, or minerals unless care is taken to prevent the onset of such deficiencies.

The consistent observations that the immediate symptoms the anemia the transient liver lesions, and the disturbances of cholesterol metabolism were all as well marked in the animals receiving the phosphatide stabilizer alone as in the animals infused with fat emulsions suggest that despite efforts to improve and purify the phosphatide stabilizer this component of the emulsion was principally responsible for any undesirable effects that were produced.

SUMMARY

- 1 Two litters of puppies were used to assay the contribution of an intravenous emulsion of 30 per cent coconut oil to energy requirements
- 2 As judged by growth and nitrogen balance growing puppies were able to utilize up to 30 per cent of their total energy requirements supplied as fat emulsion intravenously
- 3 Chemical data indicated no disturbance of plasma proteins nonprotein nitrogen, bilirubin or liver function during the infusions
- 4 A moderate normocytic anemia developed in the animals that were infused, regardless of whether they were infused with fat emulsion or just

the phosphatide stabilizer. The anemia was self-limited, responded favorably when the infusions were stopped, and in many respects resembled the anemia of infection.

5 Histologic examination of the various visceral organs revealed no abnormal lipid retention. Occasional transient, focal collections of mononuclear cells were seen in the liver for a few weeks after the infusions.

6 Chemical lipid analysis revealed no lipid retention but did indicate a disturbance of cholesterol metabolism, both in the plasma during infusion and in the livers of infused animals.

THE ELECTROPHORETIC ANALYSIS OF SERUM PROTEINS OF THE BLOOD DISCRASIAS

RAY K BROWN M D,* JOHN T READ M D, BRUCE K WISEMAN M D
AND WESLEY G FRANCE PH D
COLUMBUS, OHIO

REPORTS of the electrophoretic analysis of serum proteins in the several diseases involving the blood cells or their precursors are uncommon in the medical literature. In most instances the data presented have been recorded incidental to broader considerations of protein analysis or secondary to hematologic and histopathologic studies. Numerous reports have been made of the serum protein changes in multiple myeloma and characteristic patterns have been recognized.^{1, 2, 3, 4} However, none of these have considered the effect on the serum proteins of a recently suggested form of chemotherapy. In view of the close relationship of diseases of the reticulo endothelial system⁵ and the probable sites of formation and alteration of the serum proteins further investigation of the serum protein architecture of these related states appears indicated. In the present study the changes occurring by electrophoretic analysis of the serum proteins in various types of leucemia, pernicious anemia, infectious mononucleosis, polycythemia vera, and reticulum cell sarcoma are analyzed.

The object of this study was to learn (1) whether there is a pathognomonic serum protein architecture in one or more of the disease states under consideration and (2) if there is any correlation between the qualitative and quantitative changes observed, the related histopathology and the simpler clinical laboratory procedures.

MATERIALS

The patients used for this study were admitted to the University Hospital between Sept 1, 1946, and Dec 30, 1947. The diagnosis was established by history, physical examination, and blood and bone marrow studies using the supravital and standard Wright's staining techniques. Routine and indicated special laboratory procedures including lymph node biopsy were accomplished in each instance.

The distribution of patients into diagnostic categories was as follows: chronic myelocytic leucemia three, acute myelocytic leucemia two, chronic monocytic leucemia two, acute monocytic leucemia four, chronic lymphocytic leucemia two, acute lymphocytic leucemia one, multiple myeloma four, reticulum cell sarcoma one, polycythemia vera one, infectious mononucleosis two, pernicious anemia in relapse two. The classification of patients and the acute-ness or chronicity of a given case were determined by the cellular morphology of the peripheral blood and bone marrow in addition to the duration of illness prior to hospitalization.

METHODS

All the serum analyzed was collected under sterile precautions while the patients were in the fasting state, prior to transfusion and all but symptomatic therapy. The exception to this rule was the second sample taken from patients with myeloma who had been treated

From the Departments of Medicine and Chemistry, The Ohio State University, and the Starling Loving University Hospital.

+9 instance into which 68 per cent of normal subjects fall

with Stilbamidine. After collection the serum was refrigerated at -20°C and the analysis was made after an interval of three to twenty one days had elapsed. Aseptic technique was employed up to the time the serum was dialyzed preparatory to electrophoresis.

The frozen samples were thawed and diluted from 7 volumes to 25 volumes with 0.10 ionic strength barbiturate buffer at pH 8.6. The diluted serum was then dialyzed at a temperature of 1°C against eight to ten times its volume of buffer thrice changed during a 72 to 168 hour period. The dialyzed samples were then examined in a standard Klett electrophoresis apparatus using Longworth's technique.⁷ A 2 cc cell was employed for intervals up to 90 minutes at potential gradients of about 5 volts per centimeter at thermostat temperatures of about 10°C . Several photographic exposures of each run were made. The conductivity readings for the descending mobilities were made on the sample while those for the ascending mobilities were made on the buffer at 0°C .

Mobilities were determined from three different plates and averaged for each ascending and each descending boundary. These two figures were then averaged to give the figure reported. Concentrations were estimated by making enlargements from the photographic plates so that the new areas were from five to forty times the areas on the plates. The resulting areas were then traced with a planimeter four times and the results averaged. This procedure was done once for each ascending and descending component. The values were then converted to per cent protein using $\Delta n = 0.0200/\text{per cent}$ for albumin and $\Delta n = 0.0219/\text{per cent}$ for all globulins. Unless otherwise indicated the results given are the average of the values from the ascending and descending boundaries.

RESULTS

The data from the electrophoretic patterns of the sera of the various disease entities are set forth in Table I. Two of the normal analyses determined by us are added as well as the normal limits of mobilities, approximate relative and absolute concentrations of the various fractions.⁸

In the group of chronic leucemias listed there is a qualitative deviation from normal in the gamma globulin boundary which migrated at a slower rate than would be anticipated normally. This phenomenon was observed in all types of chronic leucemia and was present in the sera from the patient with polycythemia vera and the one with reticulum cell sarcoma. Generally the leucemic sera showed a decrease in the approximate absolute concentration of albumin. The two cases of chronic monocytic leucemia and one of the acute cases had normal albumin values. The decrease in albumin in leucemia was suggested by Keilhecker⁹ using the Howe technique of sodium sulfate precipitation. One of the patients with chronic monocytic leucemia (3a) was seen early in the disease and at that time had a high normal albumin concentration. As the disease progressed this value became markedly lower.

The leucemic sera rather uniformly demonstrated a rise in the approximate absolute and relative concentration of alpha 1 and alpha 2 globulin. The cases of reticulum cell sarcoma and polycythemia were slightly elevated in this moiety. These globulins were within normal limits in the sera of the cases of pernicious anemia and infectious mononucleosis.

The leucemic sera in general (except the chronic lymphatic) demonstrated a rise of the approximate absolute and relative concentration of beta and gamma globulin. The sera of the chronic lymphocytic leucemias were below normal for gamma globulin. Both cases of infectious mononucleosis demonstrated a rise in the relative and absolute values for gamma globulin. Sera from the patient

with reticulum cell sarcoma showed a marked rise of gamma globulin both relative and absolute, and normal beta globulin. The case of polycythemia presented low values for beta and gamma globulin. The early case of chronic monocytic leucemia and the acute monocytic leucemias demonstrate a rather marked increase in the relative gamma globulins. The cases of pernicious anemia were within normal limits for the approximate relative and absolute values of beta and gamma globulin. The total protein concentration values of all sera

Fig 1

fractionated were not comparable with those determined by the routine clinical methods, and in all but one sample the albumin-globulin ratio was lower when computed on the basis of the electrophoretic analysis. These albumin globulin ratios determined by electrophoresis fall well below the accepted normal values.¹⁰

Representative schlieren patterns are shown in Fig 1. Sera from one of the patients with acute monocytic leucemia demonstrated a small spike on the gamma globulin peak which we have not observed in normal subjects and which was seen in previous analyses of this type of sera (Fig 1, A). Fig 1, B is a pattern from a patient with chronic lymphocytic leucemia which displays a very low gamma globulin peak. One pattern (Fig 1, C) from a case of monocytic leucemia shows a notching of the alpha-2 peak which was present but not

as marked in chronic myelocytic leucemia. Fig 1, *D* is from a case of chronic myelocytic leucemia and discloses an unusual abnormality of the beta globulin spike.

The data from sera of patients having a confirmed diagnosis of multiple myeloma are presented in Table II. The architecture before treatment and in the untreated cases confirms the report by Kekwich¹ that there are two types of abnormal patterns in myeloma, a high beta globulin peak and a high gamma globulin peak. There seems to be no obvious correlation that can be made regarding any quantitative or qualitative changes in the peripheral blood protein pattern after the administration of Stilbamidine. The values are shown in Table II.

DISCUSSION

In a study of the changes in mobility of the electrophoretic pattern of serum following experimental burns, Peilmann and co-workers¹¹ found a new boundary which migrated at a slower rate than gamma globulin. Seibert¹² noted a similar component in half of the tuberculosis cases analyzed. One analysis of a patient with acute lymphocytic leucemia reported by Longworth and associates¹³ shows a tendency to slow mobility at the gamma globulin boundary. Though our cases of chronic leucemias showed this tendency to slowing, none of them displayed a separation of the peak into two parts.

The generally lowered absolute concentration of albumin has been noted in various pathologic states. Leutseher,¹⁴ in his review of the subject of electrophoresis points out the common occurrence of this trend and hence it cannot be considered as characteristic of the blood dyscrasias. This deviation from normal has been pointed out by other authors⁹⁻¹³ in both acute lymphocytic and myelocytic leucemias.

The absolute concentrations of the alpha-1 and alpha-2 globulins were generally increased over normal in the leucemias of this study. It has been stated that an increase in the alpha globulin is the first change which takes place in acute injury or infection.¹⁴ The fraction of alpha globulin which is responsible for this increase was not designated. However, it was present in the chronic as well as the acute leucemias of this series. The relative values of alpha-1 and alpha-2 globulin were similarly increased. Chow¹⁵ has shown that the rise of alpha globulin may be dependent on a fall of albumin, with normal values for the alpha globulin attained by increased protein intake and restitution of the albumin fraction. However, in several of our cases (Table I, 3,b, 4,c) there were elevated absolute alpha globulins, the albumin fraction being within normal limits. Furthermore, in one case of chronic lymphocytic leucemia administration of 50 Gm of serum albumin daily for a period of fourteen days restored the albumin to normal levels and only slightly altered the alpha 1 globulin. However, the alpha-2 globulin approximated normal and the gamma globulin content remained essentially the same. In one case of chronic myelocytic leucemia, placing the patient on a high protein diet supplemented with protein hydrolysates did not restore the albumin fraction or alter the alpha globulins appreciably even though all liver function studies were within normal limits.

A relative elevation of the gamma globulin is said to be a phenomena observed in the chronic state of disease and injury¹⁴. Our data would tend to support this, though the aberration was prominent in some acute cases and absent in a few of the chronic ones.

Both cases of chronic lymphocytic leucemia present a low value for both relative and absolute gamma globulin. Howell¹⁷ noted that leucemic individuals do not respond normally to infection or to injected antigens. Krebs¹⁸ noted diminished value of gamma globulin in simple malnutrition. One patient with chronic lymphocytic leucemia given a series of injections intravenously of typhoid vaccine did not develop antibodies as shown by the Widal test which remained negative. The administration of extract of the adrenal cortex did not alter the antibody response or the electrophoretic pattern. Repetition of this experiment after restitution of the albumin fraction did not influence the gamma globulin. Blood volume determinations¹⁹ prior to and following the administration of extract of the adrenal cortex demonstrated a moderate increase and this factor was taken into account in the latter determination. It is possible however that the pituitary adrenotrophic hormone may be involved in the gamma globulin component as Dougherty and White have pointed out in individuals with normal lymphocytes²⁰.

In the cases of monocytic leucemia and reticulum cell sarcoma, marked elevation of absolute and relative gamma globulins is seen. The explanation for this rise is obscure but may be related to the similarity of the fundamental histopathologic defect in both entities, the reticulum cell and the monoblast being closely related in the polyphyletic tree¹.

Both patients with infectious mononucleosis had elevated absolute and relative gamma globulin values and moderate diminution of the albumin fraction. The heterophile antibody was strongly positive in both cases. Although the etiology of this disease is unknown,²² much evidence has been submitted²³ demonstrating the widespread involvement of the reticulo endothelial system and other organ systems which could account for the deviation of the protein pattern from normal. The cases of pernicious anemia in relapse both demonstrated normal albumin values and normal globulin fractions. As would be expected from the approximate relative or absolute increase of the various globulin fractions, the albumin globulin ratio was consistently decreased, often to subnormal levels and even less than 1.0. All were below the range within which 68 per cent of the normal cases should fall and most were not within the limits which includes 94.5 per cent of normal subjects⁹.

In Table III there is a comparison of the electrophoretic protein determinations and the results of the clinical laboratory procedures performed in the respective disease entities. The routine laboratory protein determinations were not comparable to the total protein or A/G ratios as determined electrophoretically. The latter technique in most instances gave uniformly lower ratios than those obtained by the routine clinical laboratory methods. Nitske and Cohen²⁴ recently have demonstrated the inadequacy of the routine total protein determinations in cases of Hodgkin's disease and leucemia. These authors utilizing a methyl alcohol fractionation technique, demonstrated lower albumin and elevated globulins by this method than by the usual clinical methods.

*Rieder cells.

The correlation of the changes in protein architecture and the varied clinical laboratory procedures are particularly difficult to evaluate as the primary disease process, and many secondary effects of the disease may alter each determination. The albumin-globulin ratio or total protein determination did not bear any consistent relationship to the other procedures. The basal metabolic rate and the uric acid determinations were more consistently involved or altered in the leucemic state. These two determinations have been repeatedly investigated in this condition and are assumed to be elevated by increased protein catabolism and the breakdown of leucocytes.^{2,3} The cephalin flocculation and thymol turbidity tests were markedly elevated and the prothrombin time diminished when the excretory tests of liver function showed alteration. The thymol turbidity and cephalin flocculation tests in low titers bore no constant relationship to an abnormal A/G ratio and their aberrations may be explained in part by the occurrence of abnormal amounts of beta and gamma globulin in the sera. Cohen⁶ has demonstrated by electrophoretic studies the relationship between the thymol turbidity test and the beta globulins. The cephalin flocculation test is also reported by this author to be more closely parallel to increases of gamma globulin.

The degree of infiltration of the bone marrow by leucemic cells was determined by performing four differential counts of 200 myeloid cells each and averaging the results. By this gross determination the degree of infiltration appeared to reflect itself in a lower A/G ratio by the electrophoretic technique. No correlation between the small numbers of plasma cells in the bone marrow, lymph nodes, or autopsy specimens and the protein architecture was noted.

Investigation of myeloma serum by electrophoresis has been as thorough as that of any single disease, and its schlieren patterns can be as nearly pathognomonic as those seen in any morbid state. As stated, our results confirm those in the literature which refer to two abnormal types of myeloma patterns, one with a marked increase in the area of the beta globulin (cases 1 and 3) and the other with the major protein increase in the gamma globulin fraction (cases 2 and 4). In treated patients, the one with the beta elevation prior to treatment showed an increase in this fraction following therapy. In the gamma type no consistent effect of Stilbamidine on the protein architecture was observed. No significant changes were noted in the peripheral blood or bone marrow that could be ascribed to the therapy.

SUMMARY

The electrophoretic patterns of various blood dyscrasias are presented. The leucemic states are associated with a diminution in the approximate absolute amount of albumin and a rise in the absolute amount of globulin. The albumin-globulin ratios fall below the limits of normal in most instances. The alpha-1 and alpha-2 globulin are increased in most instances and the increase is noted with both normal and diminished total albumin values. Gamma globulin values, both absolute and relative, were elevated in monocytic leucemia, reticulum cell sarcoma, and infectious mononucleosis. Chronic lymphocytic leucemia demonstrated low relative and absolute gamma globulin values. A markedly lowered albumin-globulin ratio appears related to the degree of infiltration of the bone

marrow by leucemic cells as well as when the excretory and metabolic functions of the liver demonstrate impairment. No alteration in the serum protein architecture was noted following Stilbamidine therapy.

The authors wish to express their appreciation to Dr. Quentin Van Winkle, Ph.D., Department of Chemistry, Ohio State University, for his assistance in the preparation of the analytical data.

ELECTROLYTE PARTITION IN PATIENTS WITH EDEMA OF VARIOUS ORIGINS

QUALITATIVE AND QUANTITATIVE DEFINITION OF CATIONS AND ANIONS IN CARDIAC DECOMPENSATION

EDITH B. FARNSWORTH, M.D., and JACOB S. KRABUSIN, M.S.
CHICAGO, ILL.

WITH THE TECHNICAL ASSISTANCE OF LORA BEILE HUGHES, B.A., M.T. (ASCP)

THE role of the kidneys in the production of edema has been examined by various groups of investigators¹⁻⁴ as methods for the study of renal physiology have been developed. Although agreement has not been general concerning the sequence of events transpiring in the kidneys during the accumulation in the tissues of edema fluid, it is at least conceded that such events do transpire and that salt and water are not simply diffusing across the capillary membrane in response to an elevation of hydrostatic pressure, but are being incompletely excreted by the kidney. This concept is by no means novel, and appears in standard texts of a decade or two ago.⁵ Further clarification, however, has been delayed by the difficulties, inherent in the study of renal physiology in man, of establishing values for filtration rate sufficiently accurate to serve as a basis for the calculation of reabsorbed substances. The volume of plasma worked by the kidneys in a given period of time is so large, and the defect in salt and water excretion capable of leading to edema is relatively so small, that the significant increment tends to be lost in the physiologic variations of the mulin or mannitol clearances as we are able to determine them at the bedside. Thus, if the clearance of mulin is found to vary only to the extent of plus or minus 5 or 10 c.c. per minute, that range of error, or physiologic variation, is so large in relation to the few cubic centimeters of water or fractions of milliequivalents of sodium which represent the retention characteristic of cardiac decompensation, that physiology described in these terms must be accepted with reserves. Even more inaccessible to the clinical investigator are determinations capable of yielding conclusive information concerning the factors governing diffusion and active reabsorption in proximal and distal tubules and the stimuli which may modify these processes in disease states.

Bearing in mind these limitations, we have chosen to review in detail the alterations in urine electrolytes earlier reported in group studies⁶ confined to sodium and chloride. The depression of urinary sodium chloride ratio in cardiac failure appeared to be a constant finding implying a higher degree of specific selective tubular reabsorption than has been generally recognized. Through a more complete delineation of relationships, with varying electrolyte

Received for publication July 31, 1948.

loads it was our purpose to define the variation of electrolyte patterns and fluid balance with sufficient accuracy and completeness as to bring out characteristics tending toward a recognition of possible causal agents. In adopting an approach similar to that of Gamble we were able to avail ourselves of accepted data pertaining to the normal state.

METHODS

The two subjects selected for this study were suffering from rheumatic heart disease with congestive failure. F. W. was a 36 year old woman with mitral stenosis and insufficiency who was hospitalized in congestive failure. She was discharged improved after the experimental period but was twice rehospitalized during the subsequent six months because of fluid retention. W. S. was a 28 year old man who was first seen in the clinic and hospitalized because of advanced rheumatic heart disease with congestive failure. He was discharged improved after the reported period of study and treatment but was later admitted to a veterans hospital in terminal condition. The autopsy report indicated rheumatic involvement of the aortic and mitral valves, cardiac cirrhosis, and pulmonary infarction.

Both patients were kept in bed rest for the first fortnight of their hospital stay after which they were permitted to move about the wards as they wished. Both were allowed fluids ad libitum and both were given a low salt acid ash diet. The estimated electrolyte content of the diet, in millimols per day, was

Sodium	17.61 (average 44)
Potassium	103
Calcium	13
Magnesium	12
Iron	4
Phosphorus	63
Sulfur	32
Chloride	13-46 (average 30)

Urine specimens were collected under toluene and were kept refrigerated throughout the collection period. pH was determined on the samples as soon as they were received in the laboratory. If ammonia and phosphato determinations could not be carried out immediately aliquot samples were frozen in solid carbon dioxide and were maintained at -10° in a Dewar flask until ready for use.

Analytic procedures used in the determination of ionic constituents were for the most part as recommended by Peters and Van Slyke.⁸ All determinations were performed in duplicate or triplicate.

Sodium—Gravimetric method of Butler and Tuttle.⁹ Some of the gravimetric urinary sodium values were checked using a colorimetric adaptation of this procedure.

Potassium—Gravimetric procedure of Freeman and Burrill.¹⁰

Calcium—Microtitration by the method of Tisdall and Kramer.

Magnesium—Precipitation according to the method of Simonsen, Westover, and Wertman.¹⁰ Color development, however, was by the phosphomolybdate technique of Gomori.¹¹

Ammonia—Determination was by nesslerization following aeration from alkaline solution as in the method of Folch and Farmer.¹

Chloride—Modified Volhard-Harvey titration. In many instances, especially when protein was present, these were checked by the Van Slyke-Hiller¹² modification of Sendroy's iodometric procedure.

Phosphate—The method of Gomori¹¹ was used after decolorization and dilution. Milligrams phosphorus were converted to milliequivalents phosphate (HPO_4) by use of the appropriate factor as indicated by the pH of the sample.

Inorganic Sulfate—Turbidimetric measurement of the barium sulfate precipitate.¹⁴ This is admittedly a comparatively crude method but it gave satisfactory results and recoveries.

Recently reported deceased at home.

Organic Acids—Total twenty four hour excretion was calculated from aliquots titrated according to Van Slyke and Palmer. Creatine and creatinine were removed by shaking with Lloyd's reagent as recommended by Greenwald¹⁵. Titration was carried out between pH 8.0 and 2.7, using a glass electrode for determination of end points. Correction for the existence of some of the acid in the free form as recommended by Gamble⁷ was not made because titration curves indicated such a multiplicity of constituents that it was impossible to estimate which was the predominant acid.

Filtration rates and effective renal plasma flow were determined by the clearances of mannitol and sodium para amino hippurate. Analytic procedures were those of Corcoran and Page¹⁶ and H. W. Smith and associates¹⁷.

Serum electrolyte determinations were made by adaptations of the methods already described for urine.

Fig 1—E W electrolyte and water excretion with diuretics

RESULTS

During control periods as throughout the administration of diuretics, sodium was consistently low both in relation to intake total ionic concentration and to chloride.

Other electrolytes showed no significant variation. E W maintained a consistently higher level of calcium output than did W S, a finding consistent with previous observations that individual levels tend to be constant though variable from subject to subject.¹⁸

Of the mineral diuretics administered, ammonium chloride, potassium chloride, and potassium acetate appeared to be most effective as diuretic agents. It is notable that the maximum effect of each of these substances was reached around the third day of therapy, after which both fluid and electrolyte values declined toward control levels. For example (Fig 2), on May 23 the urine volume had risen from 1,590 to 2,230 cc with an almost identical intake, and the sodium and chloride, respectively, from 5 to 75 meq and 34 to 160 meq. After this diuretic peak, the output of salt and water declined notwithstanding the continuation of the same medication.

Fig 2—W S electrolyte and water excretion with diuretics.

Although minor responses in the sodium output were found with ammonium chloride, potassium chloride, and potassium acetate (Figs 1 and 2), the daily output tended to remain at a level far below normal values on varying salt intakes.^{5, 10}

Certain findings peculiar to the specific diuretics are notable. Calcium excretion is distinctly increased with ammonium chloride, thus W S (Table II) on May 30 showed a calcium value of 11.3 meq, with 5.9 meq before the beginning of the drug. Potassium acetate was effective in increasing water output, but the urine resulting from its administration was poor in sodium and chloride. As previously reported,¹⁰ a prompt and sustained alkalinizing effect was demonstrated.

Mercurial diuresis in W S resulted in a sodium value of 197 meq, with a chloride of 159 meq, giving a ratio of 1.2. In the case of E W, the increase in sodium excretion was substantial but not sufficient to approach a normal ratio with the chloride. In one instance (W S) the discrepancy between sodium and chloride appeared to be compensated by a threefold increase in phosphate excretion. Other electrolytes were unaffected.

Filtration rates and effective renal plasma flow are given in Table III. The filtration rate in the case of E W was within normal limits before and throughout the period of this study. That of W S, was reduced to approximately 50 per cent of normal. This marked disparity in filtering power was accepted as a desirable qualification in the selection of these subjects.

TABLE III

PATIENT	FILTRATION RATE (ML/MIN)	EFFECTIVE RENAL PLASMA FLOW (ML/MIN)
E W	119*	534*
W S	56†	303†

*Average of twelve determinations

†Average of three determinations

DISCUSSION

The choice of total quantitation of individual electrolytes as an approach to the evaluation of the kidney in edema formation appeared to offer several manifest advantages. If, indeed, the impression of various workers is correct that the kidney is implicated in the events leading to fluid retention, possibly in a prime role, then it should be determinable whether such intervention derives from the process of filtration or of reabsorption, and whether it is autonomous or responsible to some other agent.

Assuming that the serum sodium values* represent unbound sodium in these patients as in the normal, then the sodium filtered daily may be readily calculated and will be found to average 22,381 meq in the case of E W, and 9,438 meq in that of W S†. Comparison of these values with the approximate intake daily of 44 miliequivalents shows a disparity so impressive as to discourage the attempt to relate failure of excretion to failure of filtration since the latter function has with respect to the major tissue electrolytes such a wide margin of safety. The effective renal blood flow is seen to be within normal in E W and reduced by approximately 50 per cent in W S, it is evident that renal impairment as indicated by a reduced filtration rate and blood flow is not invariably associated with cardiac decompensation.

It is likewise noteworthy that impairment of the kidney would be expected to diminish renal working capacity. The demonstrated reabsorption of excess quantities of sodium, hence performance of increased osmotic work, indicates the reverse situation. It seems plausible to hypothesize, therefore

*Plasma sodium and chloride concentrations for E W were 139 meq and 102 meq respectively. These for W S at time of discharge were 119 meq and 107 meq. The low sodium level in the latter case may have been associated with the existing secondary cirrhosis.

†Filtration rate (ml/min) \times serum Na⁺ (meq/ml) \times 1440 = meq/24 hours

that the stimulus to the excessive reabsorption of sodium is specific and that it depends upon physiologic factors, chemical or humoral, rather than upon an injured or invalid kidney

The behavior of sodium with the administration of mineral diuretics as indicated in Tables I and II is predictable in terms of primary response. W/S is seen to increase urine output somewhat and concomitantly sodium output with potassium chloride, ammonium chloride, and potassium acetate. With the first two substances in patients, the sodium increase is many times greater than that of water, and, notwithstanding the administration of the chloride salt, the chloride output is less sharply increased than is the sodium. In no case did the diuretic effect last more than two to four days, although the medication was continued for several more days.

The brief duration of diuresis is an observation of clinical importance as well as physiologic interest. If potassium chloride for example, is capable of augmenting the urine volume for so short an interval of time it could well be argued that a rotation of mineral salts might be adopted in the management of chronic cardiac decompensation.

In both patients the administration of a mercurial diuretic resulted in a urine output of approximately twice that of the control levels, but the increase in sodium output was even more marked. The release of salt and water by mercurial preparations is by no means a novel observation, but the absence of significant changes in other electrolytes is a matter of considerable theoretic interest. If the augmented absorption of sodium and, to a lesser degree, chloride were a function of a factor so nonspecific as renal blood flow, it is difficult to conceive of that factor as being abolished by the administration of mercury to which a marked stimulation of renal circulation could hardly be attributed.²¹

Turning now to the excretion of potassium as shown in Tables I and II, only minor fluctuations are observed which with those of ammonia, probably reflect shifts in cation anion balance. A powerfully alkalinizing effect is noted in the urine under the influence of potassium acetate a result which serves a useful purpose in clinical practice where alkalinization by sodium salts might be undesirable. It is also of interest that when the potassium intake is elevated by the ingestion of 100 millimols of potassium salt a positive balance is established and a considerable portion of the element is held in the body.

The values for ammonia in the urine show the normal response to the ingestion of ammonium chloride. As in Grumble,⁷ Chart 29, an elevation follows that of chloride and is prolonged beyond the chloride. A tendency to inverse proportionality with sodium and potassium can be traced compatible with the classical theory of ammonia as a spacer of fixed base. This interpretation becomes open to question in the study of hepatic encephalosis presented in the following paper. Organic acids found in the urine underwent virtually no changes throughout the period of the experiments. The urine calcium, magnesium sulfate and phosphate offer no particular grounds for discussion within the framework of the present study.

The described shifts in electrolyte components should be considered as metabolic renal function tests. As such they reveal no suggestion of renal incompetence. The probability is strong, therefore, that a kidney which is able to maintain acid-base balance, preserve blood levels, and synthesize ammonia, is retaining sodium in response to factors acting upon it and not through incompetence.

Considering now the situation in terms of fluid compartments, the clinically visible increase in extracellular volume characteristic of cardiac decompensation is analogous to the situation described by Stewart and Romke² in which large infusions of isotonic sodium chloride are given daily for four days and the extracellular fluid is thus increased by approximately 80 per cent of the original volume. Examining the data reported by these investigators, we find that at the end of three days the positive fluid balance has been reversed and the urine output exceeds the water intake by almost 1 liter. The sum of the excreted sodium and chloride liberally exceeds the intake after the first twelve-hour period, and the ratio of sodium to chloride in the urine never drops below 0.89. The plasma values are not extraordinary. If it is objected that the increased venous pressure present in cardiac decompensation could not have operated in Stewart's normal subject, it might be pointed out that this situation was well simulated by the forced increase in plasma volume resulting from the daily administration of 6 to 7 liters of 0.9 per cent sodium chloride. If we may then concede that the cases are comparable with respect to the fluid compartments, we are in a position to appreciate the disturbance in excretory water and electrolyte pattern revealed in the decompensated state. It appears evident either that the normal pituitary control of fluid volumes and electrolyte concentrations is defective in the cardiac patient or that the kidney is not able to respond normally to such control.

With respect to the second possibility, namely, tubular decompensation with respect to electrolyte control, the output of individual ions other than sodium, and to a lesser degree chloride, shows no renal defect, and the responses to sharp alterations of ionic load and acid base balance indicate no deviation from normal behavior (Gamble, Charts 29-30). The data here presented might be summarized, then, by the hypothesis that the condition of heart failure with edema consists of a gross enlargement of the extracellular fluid volume, which enlargement somehow fails to elicit the normal hemostatic factors acting on renal tubules. The tubules are behaving, in fact, as normal tubules in the presence of a decreased extracellular fluid volume.

SUMMARY AND CONCLUSIONS

Two patients with rheumatic heart disease and congestive failure were studied for a period of three to four weeks by quantitative analysis of all urine electrolytes. The determinations were carried on daily, and the effects of various diuretic salts were evaluated in terms of fluid balance and urine electrolyte pattern.

Estimations of renal filtration rate and blood flow were made by the clearance of mannitol and PAH. In one patient both the filtration rate and the effective blood flow were reduced to approximately 50 per cent of normal. In the second both functions remained well within normal range.

The urine electrolyte pattern of patients in heart failure revealed a constant and specific characteristic, namely an absolute reduction in sodium excreted with a resulting diminution in the ratio of sodium to chloride.

The reduction in the sodium chloride ratio was not associated with any other constant disturbance in electrolyte excretion.

Various mineral salts were effective in promoting diuresis but this effect was of brief duration. Outputs of water and sodium which approximate the control levels were obtained in spite of the continued administration of the diuretic.

Administration of a mercurial diuretic tended to abolish sodium retention and to increase sodium excretion to a much greater degree than it did that of water.

In cardiac edema the glomerular filtration rate may be reduced or it may be maintained within normal limits.

It is proposed that the selective activities described by the data are evidence of normal response by the renal tubules to disturbances involving the regulation of fluid compartments.

We wish to express our sincere appreciation to Professor C. J. Farmer for his generous support and advice in this study.

ELECTROLYTE PARTITION IN PATIENTS WITH EDEMA OF VARIOUS ORIGINS

QUALITATIVE AND QUANTITATIVE DEFINITION OF CATIONS AND ANIONS IN HEPATIC CIRRHOSIS

LIDITH B FARNSWORTH, M.D., and JACOB S. KRAKUSIN, M.S.
CHICAGO, ILL.

WITH THE TECHNICAL ASSISTANCE OF LORA BELLE HUGHES B.A. M.T. (ASCP)

WE HAVE previously indicated the probability of sodium retention of a specific nature occurring in congestive failure and to an even greater degree in hepatic cirrhosis¹. With respect to cardiac failure we have described the renal dynamics of salt and water retention in terms of the clearances of mannitol and PAH and the quantitative evaluation of urine electrolytes. An abnormal urinary electrolyte pattern was demonstrated which was characterized by sodium retention and a reduction in the ratio of sodium to chloride². The purpose of this report is to demonstrate the qualitatively similar but quantitatively even greater retention of sodium and to some extent of chloride in hepatic cirrhosis.

METHODS

Two patients were selected in whom the clinical diagnosis of Laennec's cirrhosis was supported by liver biopsy. Both were men, 52 and 54 years of age respectively, jaundice was moderate and ascites was massive. After several days on a general diet the patients were placed on a diet containing a maximum of 15 Gm daily of sodium chloride. Mineral and mercurial diuretics were administered as indicated in Tables I and II. Paracentesis was done once or twice on each patient, and the electrolyte concentration of the ascitic fluid was determined. The cation-anion balance was quantitatively itemized from daily twenty-four hour collections of urine which were preserved under toluene and refrigerated. Analytic methods employed in the determination of ammonia, magnesium, calcium, chloride, phosphate, sulfate, and organic acids are described in the preceding paper². Sodium and potassium values were determined by the Beckman flame photometer.

A few data were included from a third patient B.G., of the same sex and age group in whom complete collections were difficult because of incontinence and illiteracy. The urine values are therefore scattered. The data are included because of the more regular blood studies available.

RESULTS

The excretion of sodium was found to be exceedingly low with all dietary loads. The urinary suppression of sodium, regardless of daily salt ingested, was even more refractory to diuretic treatment in these patients than in the patients in congestive failure reported in the foregoing paper.

Fluid output was also consistently low and the administration of mercurial diuretics resulted only rarely in a slight diminution in body weight, in contrast with the effect in heart failure.

‡The low salt diet was maintained for the duration of the experimental period

Chloride output was also exceedingly low and tended to be lower than in heart failure. With relation to sodium output, however, the diminution was less extreme, hence the sodium-chloride ratio remained lower than in normal subjects or in congestive failure. The use of mercurial diuretics caused a greater chloride than sodium excretion. This increase in chloride output was in turn frequently associated with an increase in urine potassium.

The excretion of ammonia in response to the administration of ammonium chloride was very different in the two subjects. D. E. showed the typical delayed but protracted increase in urine ammonia (Gamble, Chart 29),³ and J. S. appeared unable to synthesize ammonia.

Administration of potassium acetate, 100 meq daily, was associated with a low ammonia output, in the encephalic subjects as in the cardiac patient to whom the medication was given.

Sulfate excretion tended to be low, a finding which is presumably to be correlated with interference with metabolism of sulphur containing amino acids in the liver.

The excretions of calcium and magnesium were variable in both patients. The determinant of these variations appeared to be chloride rather than phosphate excretion.

DISCUSSION

On inspection the data resemble rather closely those derived from the patients in cardiac failure presented in the preceding paper. The initial control periods, without dietary restriction of salt, indicate a retention of sodium, chloride, and water. These positive balances persist notwithstanding the imposition of electrolyte loads by mineral diuretic medication and in spite of the frequent administration of mercurial diuretics. These facts parallel the findings in congestive failure, and establish the fact that in Laennec's cirrhosis sodium retention rather than hypoproteinemia is a major determinant of ascites and edema. Here again, in cirrhosis as in cardiac failure, the pattern is not one solely of filtration of plasma water and electrolytes through the capillary wall, but a more complicated sequence in which the reabsorptive activity of the renal tubules plays a substantial part. As in the cardiac subject, the primary or secondary order of such renal participation becomes a concern of fundamental importance.

While the retention of salt and water lends similarity to the two entities, certain sharp differences appear. First, the urinary sodium concentrations tend to be lower in our three patients with cirrhosis than in congestive failure, indeed, during the control period on a general diet all patients showed a total absence of sodium when the gravimetric procedure was attempted on unconcentrated urine. Although the absolute chloride content was also markedly reduced, it was still high enough to yield a sodium-chloride ratio which was decidedly lower than those found in cardiac patients. The response to mercurial diuretics indicates a more striking divergence. Figs 1 and 2 show only minimal variations in urine volume during the administration on alternate days of Mercur hydri, and the body weight appears to be unaffected by medical diuretics.

Fig 1—D E electrolyte and water excretion with diuretics

The excretion of sodium is mildly augmented by mercury but, contrary to experience with patients in heart failure the effect on chloride is consistently more marked, and hence the ratio sodium chloride is not restored to normal at any time. These observations pose several questions: firstly, are they the results of incompetent kidneys? second, are they due to abnormalities of electrolyte concentration in one or all of the fluid compartments?

With respect to the functional integrity of the kidneys the clearance rates of mannitol and PAH are given in Table III along with the blood chemistry values. Although substantially below the normal they can hardly be taken to indicate renal decompensation. The fluctuation of urine values of ammonia in

urine excretion of sodium was almost entirely suppressed. The data given in Tables III and IV show normal concentrations in plasma and ascitic fluid of sodium, potassium and chloride in the case of D E, with similar values for J S with the exception of the plasma sodium of 124 meq. Plasma sodium values for B G declined from 141 meq on a free diet to 120 meq on a low sodium diet. At those two levels the urine output of sodium was 0.1 meq and 0.4 meq respectively. The volume of the extracellular fluid compartment however was grossly enlarged, as evidenced by the massive dependent edema as well as ascites of all patients. Here again a situation exists which would normally elicit a spontaneous diuresis since it is the major function of the renal excretory mechanism to defend not only the concentration but the volume of the extracellular fluid. With respect to salt and water then the kidneys are behaving as if the body were dehydrated. The paradox is essentially the same as was found to exist in the state of heart failure only to a more marked degree.

The findings which we have described support the impression expressed by recent investigators^{1, 2} that abnormalities in water distribution in cirrhosis cannot be accounted for solely on the basis of plasma protein deficiency and diminished colloid osmotic pressure.

CONCLUSIONS

The urinary electrolyte pattern in hepatic cirrhosis is similar to that in cardiac failure. The renal retention of salt and water long recognized in heart failure, is present to a more marked degree in hepatic cirrhosis.

As in heart failure, the mannitol and PAH clearances may be somewhat reduced, but the metabolic functions of the kidneys are essentially unaffected and other urinary electrolytes exhibit the normal responses to variation in electrolyte intake.

Water and salt diuresis was minimal after administration of mercurial diuretics. One instance is shown however in which a lavish diuresis of electrolytes was initiated by Mercurydim.

In addition to the hydrostatic factors operating in cirrhosis the genesis of edema and ascites in this condition is also attributable to a retention of sodium and water. This urinary suppression of sodium is independent of the plasma concentration. Since the competence of the kidneys has been demonstrated by clearance determinations of mannitol and PAH as well as by quantitation of urine electrolytes, the hypothesis is suggested that the stimulus to salt and water retention is specific and that the same stimulus is probably acting in both diseases.

We extend our warm thanks to Dr. A. C. Coreoran for his help in the preparation of this paper.

Fig 2—J S electrolyte and water excretion with diuretics

response to ammonium chloride, potassium in response to potassium salts, and sodium in response to ammonium chloride are in themselves renal function tests and offer evidence that the kidneys are not in default. Attention should be called parenthetically to the differences in the two records toward the end of the experimental period. D E tolerated the ammonium chloride, 220 meq daily, for five days, and underwent a dramatic diuresis of electrolytes, whereas J S became comatose after three days on similar amounts of ammonium chloride and the medication was discontinued when the plasma CO₂ reached 17 meq per liter. Although the urine pH of this patient did not decrease below that of D E under the same conditions, J S appeared to be unable to synthesize ammonia and continued to put out a small volume of urine, poor in electrolytes, in spite of clearance values almost identical with those of D E. The reason for this discrepancy is probably to be found in the poor nutritional condition and extreme anorexia which characterized his hospital course, in contradistinction to D E who ate heartily throughout the period of observation.

The second question which we have proposed concerns the volume and electrolyte composition of the fluid compartments in cirrhosis. In our experience patients with cirrhosis have shown normal or only slightly lowered plasma sodium while on a general diet, reduction in intake has resulted, in several instances, in markedly reduced levels. At all plasma concentrations, however, the

ON THE EFFICACY AND SAFETY OF GLYCINE ADMINISTERED BY VEIN

GEORGE L. COLLENTINE, JR., B.S. M.D.
MILWAUKEE, WIS.

THE current rapidly increasing use of amino acid preparations by the intravenous route has suggested a more specific study of certain effects of the simplest of these compounds, glycine, when administered by this method. Although not a significant constituent of the available commercial products since these are principally acid or enzymic hydrolysates of casein which contains little glycine, this amino acid deserves consideration.

Because it is readily synthesized in apparently adequate amounts by the normal human body, glycine falls into the classification of 'nonessential' amino acids—a connotation unfortunately accepted by many to be synonymous with "unimportant" which may explain the lack of attention to this compound in the field of parenteral amino acid preparations. Glycine, however, is a component of many of the body proteins (collagen is rich in glycine) its roles in the syntheses of such nonprotein substances as creatine,¹ glycocholic acid, glutathione,² the protoporphyrin portion of hemoglobin³ and uric acid⁴ have received widespread attention and confirmation in isotope studies during the last few years. In each instance the ingestion of glycine tagged with N¹⁵ has been followed so quickly by the appearance of labeled molecules of these products as to indicate the direct participation of this amino acid in their syntheses. Glycine, moreover, has long been known to take a leading part in the detoxication mechanism applied by the body against a large number of potentially harmful products of metabolism. Representative of this action is the conjugation of benzoic acid, an oxidation product of many toxic aromatic compounds, with glycine to form hippuric acid.

The Quick test of liver function is based on the relationship between the functional state of that organ and the capacity for synthesis of hippuric acid from ingested benzoic acid. It has been shown that supplying extra glycine by mouth during the test will in some instances appreciably increase the hippuric acid output even when it is seriously diminished in liver disease. Thus it is evident that the actual ability of the liver cell to bring about the conjugation may not be impaired, but that the rate of synthesis of glycine is the critical consideration. Depression of this rate occurs in normal pregnancy to the extent of 15 per cent below normal⁵ and in toxemias of pregnancy and other conditions the ability to detoxicate is much more seriously impaired.

Here again isotope studies have shed some light upon the mechanism involved. Simultaneous feeding of sodium benzoate and an excess of labeled

From the Department of Biochemistry, Marquette University School of Medicine.

Received for publication March 29 1948

glycine resulted in the utilization of exogenous amino acid for about one third of the hippuric acid synthesis.⁸ The body must have supplied the remaining two-thirds required for the detoxication. Very little is known of the source or precursors of this endogenous supply. The observation of Christensen and co-workers that the ingestion of sodium benzoate is followed by a depression of the fasting blood glycine level in human beings⁹ has been confirmed in this laboratory. From this it would seem that the body maintains its glycine reserves freely mobile in the blood stream, and depends upon rapid synthesis to meet specific demands for detoxication and other purposes.

Recently, Gubner and associates¹⁰ have employed the specific dynamic action of glycine to bring about some conceivably desirable changes in peripheral blood flow. Their work was based on the correlations that have been established between the metabolic rate and cardiac output and peripheral blood flow.^{11, 12} By means of skin temperature recordings, oscillometric readings, plethysmographs, and oxygen consumption determinations they have shown that the increased heat production and oxygen consumption that follow the ingestion of glycine are accompanied by a maximal increase in circulation to the extremities. The skin temperature changes produced are equivalent to those obtained with nerve block and are consistently greater in duration and degree than those caused by alcohol. The presence of peripheral vascular disease in some of their subjects did not alter the response.

This considerable multiplicity of important metabolic functions, viewed in the knowledge that the rate of synthesis of glycine is depressed in a variety of conditions, lends plausibility to the idea that reasonable indications may exist for the supplying of glycine by veins when enteral nutrition is precluded. The studies to follow were undertaken to investigate some effects of glycine administered intravenously.

EXPERIMENTAL

For the determination of glycine concentrations in blood and urine, the specific colorimetric micromethod of Alexander, Landwehr, and Sehgmaw¹³ was employed, with the only difference that a Cenco photometer was used instead of the suggested Evelyn or Klett instruments. This method depends upon the distillation conversion of all free glycine into formaldehyde by the action of anhydrous, the resulting formaldehyde being allowed to react with chromotropic acid to produce a measurable color. Metabolism determinations were made with a standard waterless respirometer.

I. Two female dogs previously fasted for fourteen hours were given infusions of 5 per cent or 10 per cent glycine in physiologic saline solution by simple intravenous drip, the rate of flow being regulated to take thirty minutes. Blood samples were withdrawn immediately before the infusion, immediately afterward, then one and two hours later. Catheterized urine specimens were obtained for the hour preceding administration of glycine and at hourly intervals after the drip began. Two doses were employed: one amounted to 0.5 Gm. of glycine per kilogram of body weight and the other to 1.0 Gm. per kilogram. With the latter dose, both dogs showed signs of distress such as bradycardia, extrasystoles, excessive salivation, and vomiting at the conclusion of the infusion. These signs disappeared within the next half hour, and on a subsequent occasion one of the dogs tolerated this dose without apparent ill effect. Table I is a record of urinary output of glycine during four of the preceding experiments on one of the dogs.

Total	3.89 mg	308.7 mg	1702.7 mg	1436.9 mg

Infusion begun at end of control hour 1 duration thirty minutes

Fig 1 —Blood concentration curves in dog and human being (see text)

II Eight normal adults, fasting for twelve hours were given a total of about twenty intravenous doses of glycine ranging from 12 to 10 Gm on a basis of 0.2 Gm per kilogram of body weight with the method of administration similar to that in the previous experiments. One subject was given a dose of 30 Gm (0.4 Gm per kilogram) and at the end of the half hour injection he noted a feeling of warmth and tingling in the extremities, some increased salivation slight nausea and heightenedness all of which passed within a half hour. No noteworthy subjective manifestations were mentioned by subjects given the smaller dose except the feeling of tingling, which was inconstant.

Blood specimens were taken immediately before and after the infusion and at one, two and three hours thereafter. Duplicate tracings to determine basal metabolism were made before administration of glycine and single tracings were made before each blood withdrawal.

It was soon noted that the curves of blood concentrations obtained on these rather arbitrarily selected doses in dogs and human beings showed striking similarity. Indeed, when average curves for each series were drawn, they could be superimposed for presentation. In Fig 1, curve A represents the average of six closely comparable curves obtained in dogs with the smaller doses (0.5 Gm per kilogram) and of a dozen or more similar curves

Fig 2—Per cent increase in oxygen consumption (A) following dose of 0.4 Gm per kilogram (B) same subject as (A) after dose of 0.2 Gm per kilogram others after latter dose

from human beings given 0.2 Gm of glycine per kilogram. Curve B was obtained with the doses that produced untoward symptoms in both dog and human being (1.0 and 0.4 Gm per kilogram respectively).

In Fig 2, some curves showing per cent of increase in rate of oxygen consumption above the basal level are presented. A control experiment, using only intravenous saline without glycine, was performed with one student who acted as subject for the glycine experiment on six occasions. This subject showed a perfectly constant rate of metabolism throughout the control test period, but responded to the addition of glycine with increases similar to those presented.

III Blood glycine concentration curves were obtained with 0.2 Gm per kilogram dose in two patients with clinical chronic hepatitis (portal cirrhosis). Diagnosis in each case had been confirmed by punch liver biopsy and by abnormal responses to at least three different liver function tests (bromsulfalein, hippuric acid thymol turbidity and cephalin flocculation). From the data in Table IV it may be seen that the curves were practically identical to each other and to the curve presented as the average of all normal adults. The fasting blood levels are toward the high range of normal but the response to the infusion is strikingly close to the average.

COMMENT

The intravenous doses of glycine required to produce signs of distress in dogs (10 Gm per kilogram) correspond closely to those reported by Lewis,¹⁴ Riker and Gold¹⁵ and Loomis and Quiek¹⁶. The dog that showed signs from the dose on one occasion and not on a subsequent trial had a slightly lower minimum blood level on the second occasion (70.0 mg per 100

ml as compared with 740 on the first) It is noteworthy that the blood concentration producing symptoms is similar in the dog and man, although the dose per unit of body weight required to produce them is two and one half times greater in the dog In view of the fact that all subjects tolerated the 12 to 16 Gm (0.2 Gm per kilogram) intravenous doses, even in the short injection time employed, it may be said that this represents a safe dose

Christensen and associates⁹ and Gutman and Alexander,¹⁷ the only investigators who have published results of specific determinations of glycine in blood by the method used here, have reported fasting levels slightly lower than those obtained in these experiments Initial levels in their subjects ranged between 18 and 23 mg, averaging 20, while the results presented here are based on fasting levels of 24 to 28, averaging 26 There was a remarkable constancy of this characteristic in individuals tested repeatedly

The apparently "normal" blood level curves obtained in the two subjects with cirrhosis are considered an indication that a "glycine tolerance test" along these lines would have no diagnostic value in this disease, where the deficiency with respect to glycine is in the rate of supply rather than in the metabolism of the amino acid provided exogenously In this connection, however, the work of Weichmann and Dominick on tolerance of intravenous glycine in health and diabetes is worthy of mention They have demonstrated that following the administration of glycine the amino acid nitrogen content of serum returns within normal limits much more rapidly in healthy than in diabetic subjects¹⁸ Insulin caused a faster return Duplication of these experiments, using the specific glycine determination, might produce even more clear cut results

Pitts has shown that of the four amino acids (glycine, alanine, glutamic acid, and arginine) the rate of renal tubular reabsorption is highest for glycine¹⁹ This probably accounts for the strikingly low excretion of unchanged glycine even when the blood concentration is as much as thirty times the fasting level

The abrupt drop in the blood level, without corresponding urinary excretion, during the first hour after the infusion is an indication of the rapidity with which the glycine is metabolized The work involved in this task of deamination and redistribution of the resulting fractions is reflected in the elevated caloric production No previous reports of specific dynamic action of amino acids administered intravenously to human beings could be found in the literature Inasmuch as the necessary total nitrogen metabolism studies were not undertaken, it is not possible to express the results obtained in terms that relate them to the quantity of given substance metabolized, as suggested by Peters and Van Slyke The metabolism effect obtained here with glycine administered by vein corresponds generally in magnitude with that reported by Gubner and associates to follow oral ingestion

Lusk showed conclusively that the increased heat production of specific dynamic action cannot be utilized for the performance of work Nevertheless, the possibility remains that this heightened state of metabolic activity

which can be induced by the administration of a practically nontoxic, readily available amino acid might well be desirable for example, in medical and surgical convalescents. The associated augmentation of peripheral blood flow cannot be ignored. In any condition in which the depression of the body's ability to supply glycine is known or expected (as in preoperative fortification of the liver for biliary tract surgery), the body should profit from parenteral glycine in much the same manner as it does from glucose.

SUMMARY

Glycine plays an important role in the synthesis of body protein creatine, glycochole acid, glutathione, uric acid, and heme. It is apparently essential in detoxication and exhibits remarkable versatility in general metabolism. The possibility of depression of glycine synthesis in abnormal states should be recognized.

Blood and urine studies following the intravenous administration of glycine are presented to demonstrate the rapidity of its metabolism and its lack of toxicity even in high blood concentrations. Specific dynamic effect is obtained when it is given by this route.

As an adjunct to the usual parenteral protein therapy glycine may be administered intravenously with safety and with beneficial effect when oral feeding is not possible.

DETERMINATION OF ANTIBODY CONTENT OF LYMPHOID CELL EXTRACTS

FRANCES SPAR, B A MS
BETHESDA MD

RECENT investigations¹ of the role of lymphocytes in antibody formation have focused attention on the technical difficulties of serologic titration with small volumes of cells. The present work represents an investigation of the requirements of serologic technique using the small cell volume available from the lymph or lymph nodes of experimental animals.

The lymph was obtained from the efferent vessel of the popliteal node of a rabbit. The cell content of the lymph was determined using a white blood cell pipette and a standard counting chamber as used for peripheral blood examination. The total cell volume was estimated by the formula of Harris and co-workers¹ in which cell volume in milliliters equals the cell count in thousands times 0.002 times the number of milliliters of lymph. The total cell volume available in our experiments varied from 0.001 to 0.01 milliliter. It was felt that the smallest volume that could be pipetted with accuracy in this work was 0.05 milliliter. Employing the principle of Hemolytic System Adjustments² the following procedure for diluting lymph extracts was followed using 0.2 ml pipettes graduated in 0.001 ml and test tubes 10 by 75 millimeters.

TUBE	SALINE	FACTOR
1 0.05 ml substance	---	1
2 0.05 ml substance	0.05 mix remove 0.05 ml to control tube	2
3 0.05 ml substance	0.1 mix discard 0.1 ml	3
4 0.05 ml substance	0.15 mix transfer 0.05 ml to tubes 5, 6, 7	4
5 0.05 from tube 4	0.05 mix discard 0.05 ml	8
6 0.05 from tube 4	0.10 mix discard 0.10 ml	12
7 0.05 from tube 4	0.15 mix transfer 0.05 ml to tubes 8, 9, 10	16
8 0.05 from tube 4	0.05 mix discard 0.05 ml	32
9 0.05 from tube 4	0.10 mix discard 0.10 ml	48
10 0.05 from tube 4	0.15 mix transfer 0.05 ml to tubes 11, 12, 13	64

To each tube 0.05 ml of *Salmonella typhimurium* antigen (density equal to McFarland tube number 5) was added. Vials were shaken and incubated in a water bath at 37° C for two hours, were left in the cold room overnight and read the following morning.

A comparison of this method of dilution and the usual macromethod of employing 0.2 ml of material in serial dilution in 0.2 ml of saline is given on the following page.

Lymphoid cell extracts were prepared by freezing and thawing, with and without preliminary washing of the cells. After the lymph had been drawn, and the count taken, the rest of the lymph was measured into a small test tube and centrifuged at 2,000 revolutions per minute for five minutes to sediment the cells. The lymph was withdrawn with a capillary pipette and saved for testing, the cells remained in the same tube. To the estimated volume of cells, a volume of saline was added which would give sufficient material for testing with a minimal dilution factor for the cells. Lysis of the lymph cells to extract antibodies was effected by freezing with dry ice and thawing at 37° C. This process was repeated three times. A clear supernatant was obtained by centrifugation and used in the serologic test outlined.

In addition, experiments were carried out in which the lymph was divided into two portions. One portion was treated as previously outlined. In the procedure with the other, instead of extracting the cells in the saline, they were gently resuspended and centrifuged, and the saline was removed and saved for testing. The cells were resuspended in a like volume of saline and subjected to the lysing process.

In the example of results given below, the rabbit had been injected in the left foot pad with 1 cc of *S. typhimurium* suspension equal in density to McFarland tube number five.

Antibody titer of unwashed cells of lymph from right popliteal node	1 102
Antibody titer of unwashed cells of lymph from left popliteal node	1 70
Antibody titer of washed cells of lymph from right popliteal node	Negative
Antibody titer of washed cells of lymph from left popliteal node	1 13
Antibody titer of saline wash of right cells	1 10
Antibody titer of saline wash of left cells	1 13
Antibody titer of right lymph	1 160
Antibody titer of left lymph	1 160
Antibody titer of serum	1 480

It appears that the apparent high titer of extracts of cells of lymph may be entirely or in large part due to small amounts of lymph adherent to unwashed cells, or to the sides of the tube. Therefore these effects were investigated further.

Four tenths milliliter of a serum with a titer of 1 512 was placed in a small test tube and the serum was carefully removed with a capillary pipette. A volume of 0.05 ml saline was delivered into the same test tube and removed with a capillary pipette, whereupon a second volume 0.05 ml volume of saline was added. In serologic measurements the first saline wash was positive in a

dilution 1:256, and second wash was positive in a dilution of 1:12. Had the titer of the salines been calculated in reference to a hypothetical volume of cells (0.0025 ml) which had been frozen and thawed to extract immune bodies the titer of the first wash would have been 1:2856 the second wash 1:324. Hence the presence of traces of fluids containing immune bodies greatly distorts titers which are computed with reference to extracts of extremely small volumes of cells.

Again multiple washes were used to eliminate the effects of traces of body fluids in an investigation of the extracts of cells of the popliteal node. The detailed procedure was as follows: The popliteal node was weighed and placed in a small beaker with a volume of saline nine to nineteen times its weight. The node was cut sufficiently to permit the release of the cells yet leave the node tissue in one minced section rendering filtration unnecessary. After a cell count had been taken the cell saline suspension was measured into a small test tube and centrifuged ($1000 \times$ gravity) for five minutes. The supernatant was carefully withdrawn (referred to below as wash 1) and saved for testing. Droplets of fluid observed on the sides of the test tube were removed with a clean cotton swab. Employing the same test tube the volume of cells (computed as count in thousands \times volume in milliliters $\times 0.0002$) was resuspended in fresh saline an amount which was a multiple of the volume of cells and gave sufficient material for testing. After this second suspension had been centrifuged the supernatant was withdrawn and saved as wash 2.

The cells were then suspended in an amount of distilled water equivalent to half of wash 2. After the cells had been lysed through the combined effects of distilled water and alternate freezing and thawing a volume of 1.7 per cent sodium chloride solution equal to the amount of distilled water was added. The mixture was shaken, allowed to stand then centrifuged. The microtechnique was used to estimate the amount of antibody present in the cell extract as well as the washes. A typical result is presented.

Wash 1 titer 1:80 (proportion computed for weight of node)

Wash 2 titer 1:30 (proportion computed for volume of cells)

Cell extract titer 1:16 (proportion computed for volume of cells)

SUMMARY

The present work represents an investigation of the requirements of serologic technique using the small cell volume available from lymph or lymph nodes of experimental animals.

The experience of this laboratory indicates that especial care must be exercised in the interpretation of titers because small errors of fluid containing antibodies may greatly distort results if these are expressed in terms of cell volume.

THE EFFECT OF NITROGEN MUSTARD AND X IRRADIATION ON BLOOD COAGULATION

LEON O JACOBSON, M D , EDNA K MARKS, EVELYN GASTON,
J GARROTT ALLEN, M D , AND MATTHEW H BLOCK, M D *
CHICAGO, ILL

INTRODUCTION

ALLEN, Jacobson, and associates¹ reported that exposure to ionizing radiations produced a prolonged whole-blood coagulation time (Lee-White) in dogs and in human beings as a result of the appearance in the blood of an anti-coagulant biologically similar to heparin. More recently Smith, Jacobson, and co-workers observed a prolonged whole-blood coagulation time in five patients given therapeutic doses of nitrogen mustard (methyl-bis-(β -chloroethyl) amine hydrochloride). This clotting defect was identical to that reported by Allen and co-workers in the dog and human being following exposure to ionizing radiation in that the clotting time could be returned to normal both in vivo and in vitro by specific antiheparin substances such as toluidine blue and protamine sulfate. The prothrombin time and the calcium and fibrinogen blood levels were within normal limits in these subjects but each had a severe leucopenia and thrombocytopenia.

Reports by Jacobson and associates,⁶ Spurr and co-workers,⁷ and Block and co-workers⁸ have pointed out the toxic effects of nitrogen mustard on the blood and blood-forming tissue of patients who were given this drug therapeutically. Although these authors reported pancytopenia, a prolonged bleeding time, ecchymosis and cutaneous and mucous membrane petechiae, no alteration of significance in the whole-blood coagulation time was described.

The dosage and schedule of administration of nitrogen mustard in the five patients referred to were as follows. Two patients were given 0.1 mg per kilogram of body weight intravenously on four consecutive days. The injections were administered twenty-four hours apart and the total dose in one was 25.4 mg and in the other 26.8 milligrams. One patient received four injections of 0.1 mg per kilogram of body weight at intervals of twelve hours, the total dose was 22.4 milligrams. One patient was given four injections of 0.1 mg per kilogram at intervals of seven hours, the total dose was 20.0 milligrams. One patient was given two injections of 0.3 mg per kilogram, each six hours apart, the total dose was 3.8 milligrams. The fact that a severe hemorrhagic state, terminating fatally, developed in all of these five patients led us to suspect an impurity or some intramolecular transformation in the drug or unusual sensitivity of the patient to the drug. However, other pa-

tients treated with the same lot number of the drug and with similar total dosage did not manifest this clotting defect nor has a new supply of this drug produced such a toxic reaction.

Because of the rather widespread clinical use of nitrogen mustard in the treatment especially of neoplastic diseases of the hemopoietic system and the serious implication of hemorrhage, studies in experimental animals were undertaken to elucidate further this effect.

MATERIALS AND METHODS

Swift's snuffle free rabbits of uniform age and weight (2.5 to 3 kilograms) were used in this study. Previous studies with nitrogen mustard in our laboratories¹⁰ indicated that a single intravenous dose of 30 mg per kilogram of body weight produced a destructive effect on the hemopoietic system of this strain of rabbits approximately equivalent to 800 r total body X irradiation. The effect of both of these agents on the whole blood coagulation was studied simultaneously for comparative purposes.

Technique of Nitrogen Mustard Administration—A dose of 3 mg of nitrogen mustard per kilogram of body weight was injected slowly into the marginal ear vein of the rabbit immediately after the chemical had been dissolved in physiologic saline. A concentration of 1 mg of the drug per 1 cc of saline was used since this concentration produced no sloughing of the ear tissue and did not obliterate the ear vein.

Technique of X Irradiation—The X rays administered in these experiments were generated on a 200 kv machine operating at 15 milliamperes. A 0.5 mm copper filter and a 1 mm aluminum filter were used. The half value layer in copper of the filtered beam was 0.98 millimeter. The exposure was measured with a Victoreen condenser meter equipped with a 100 r chamber. Measurements were made in air within a treatment box at the position occupied by the center of the animal's body. Victoreen chambers of 250 r full scale readings were used as monitors.

Hematologic Studies—

Whole Blood Clotting Time—The clotting time of the whole blood was determined at room temperature by a modification of the Lee White method.¹⁰ Whole blood (0.5 cc amounts) was measured into five or six small test tubes (10 by 75 mm) and 1 cc amounts were pipetted into two or three large test tubes (13 by 100 mm). The larger tubes were not examined until clotting had been established in the small tubes. The time which elapsed between obtaining the blood (first appearance in the syringe) by cardiocentesis and the clotting of two consecutive tubes which had not previously been manipulated was considered to be the whole blood clotting time, and the blood was considered to be clotted when it remained firm upon inversion of the tube.

Platelet Determination—Platelet counts were made by drawing blood to the 0.5 mark in a white blood diluting pipette and diluting to the 11 mark with a 18 per cent solution of freshly prepared sodium citrate. The pipette was gently shaken for one minute after which the entire content of the pipette was allowed to flow into a small Lusteroid conical shaped tube. The tube was set aside at room temperature until sedimentation of the red cells had occurred. The platelet counts were then made on the plasma whenever time permitted (within twenty four hours).

TABLE I AMOUNTS OF PROTAMINE SULFATE AND BLOOD USED IN THE
HEPARIN TOLERANCE TEST

Heparinized blood* (c.c.)	0.5	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25	0.25
Amount of protamine sulfate† (c.c.)	0.01	0.02	0.03	0.035	0.04	0.045	0.05	0.055	0.06	0.07

0.05 c.c. liquid heparin in 3.0 c.c. blood
11 mg protamine sulfate in 2 c.c. normal saline

Heparin Tolerance Test—Modifications of the heparin tolerance technique developed by Allen and co workers⁴ were necessary to avoid the repeated withdrawal of large amounts of blood from rabbits. Protamine sulfate which was weighed on an analytical balance was dissolved in physiologic saline in a concentration of 1 mg of protamine to 2 cc of saline. This solution, which was prepared every other day, was titrated into a series of ten small test tubes (10 by 75 mm) as shown in Table I. In performing the test, 35 cc of blood obtained by cardiocentesis were immediately added to a tube containing exactly 0.02 cc of liquid heparin and gently inverted twenty times. Immediately thereafter, 0.25 cc of this heparinized blood was added to tubes containing the graduated amounts of protamine sulfate described. Each tube then was shaken gently and set aside at room temperature. At the end of one, three, and twenty-four hours, readings were made to determine the minimum amount of protamine sulfate necessary to cause the blood to clot. Normal rabbit blood requires 17.5 to 22.5 γ protamine to bind the heparin in the amounts used. With one exception, the one-hour readings are reported in this communication.

Prothrombin Studies—Prothrombin determinations were made according to the Link Shapiro modification of Quick's method.¹¹ Commercial thromboplastin (Maltine) and both diluted and undiluted blood plasma were used in these determinations.

Calcium and Fibrinogen—Calcium determinations were made on the blood serum by precipitating the calcium as an oxalate according to the method of Clark and Collip.¹² The presence of fibrinogen was noted by heating the plasma to 58° C in a water bath. No quantitative fibrinogen determinations were made.

GENERAL PROCEDURE

Rabbits were divided into three groups for the nitrogen mustard experiments. Group I received nitrogen mustard (3 or 4 mg per kilogram of body weight) intravenously. Group II received 3 or 4 cc of physiologic saline per kilogram of body weight intravenously. Group III consisted of normal untreated animals that received neither nitrogen mustard nor saline. Since saline was used as a solvent for the nitrogen mustard, Group II animals that received saline served as a control for Group I, while Group III which received neither nitrogen mustard nor saline served as a control for both Groups I and II.

Approximately 10 cc of blood were withdrawn from the rabbit by cardiocentesis using a dry 18 gauge needle and a dry 10 cc syringe. Three and one-half cubic centimeters of this blood were immediately transferred to a graduated centrifuge tube containing 0.02 cc of liquid heparin for the heparin tolerance test, 0.9 cc of blood was transferred to a tube containing 0.1 cc of sodium oxalate for the prothrombin determination, the remaining blood was pipetted in 0.5 and 1 cc amounts into a series of test tubes for the whole blood clotting time as previously described.

Only one attempt was made to obtain blood from the heart of the rabbit. When that was unsuccessful no further attempts were made to obtain blood until the animal had rested (at least two hours).

After a prolonged clotting time and an abnormal heparin tolerance test had been established, one group of animals was given toluidine blue (64 per cent dye content) intravenously, while another group was treated with protamine sulfate. Both toluidine blue and protamine sulfate were given in concentrations of 1 mg per 1 cc saline. The doses of protamine or toluidine blue given per injection were 3 and 4, and 2 and 2.5 mg, respectively, per kilo

gram of body weight. One group of animals that received 3 mg of nitrogen mustard per kilogram of body weight remained untreated for comparative purposes.

Animals exposed to 800 r total body X radiation were treated similarly, one group receiving either toluidine blue or protamine after a prolonged clotting time had been established, while another group remained untreated.

Fig 1A—Average clotting time (1 cc blood) platelet values, and heparin tolerance test (one hour results) in normal rabbits (blood obtained by cardiocentesis)

Fig 1B—Clotting time (1 cc blood) platelet values and heparin tolerance test (one hour results) in one normal control rabbit (08) (blood obtained by cardiocentesis)

RESULTS

The mean average of the whole-blood clotting time in normal untreated rabbits varied from 8 to 16 minutes in tubes containing 1 cc of whole blood. The platelets of the normal rabbits varied considerably but were usually between 250,000 to 500,000 per cubic millimeter. The heparin tolerance test gave fairly constant results in normal rabbits, 17.5 to 22.5 γ of protamine sulfate were necessary to produce a clot in heparinized blood prepared as outlined. Thus clotting occurred normally in tube 4, 5, or 6 (see Table I). The mean average results of the whole-blood clotting time, platelets per cubic millimeter, and the heparin tolerance results of seven untreated normal animals are shown in Figs 1A and 1B. Fig 1A illustrates the fluctuations in these determinations which a single animal may exhibit during a twenty-four day period of observation. Normal animals on which such determinations are made at frequent intervals over a period of thirty days or more usually exhibit less variation than this individual animal illustrates.

Effect of Nitrogen Mustard—

Clotting Time—A prolonged clotting time of the whole blood occurred after the intravenous injections of 3 or 4 mg of nitrogen mustard per kilogram of body weight. Fig 2 shows the effect on the clotting time of sixteen rabbits given intravenous doses of 3 mg per kilogram. An increase in the length of the clotting time was present twenty-four hours after nitrogen mustard administration, reached a peak in *circa* four to seven days, remained high about ten days, and returned to a normal value in the surviving animals by two weeks. The effect of nitrogen mustard on the clotting time of an individual animal is shown in Fig 3. The pattern of individual response is similar to the mean values shown in Fig 2 except that the clotting time was not infrequently prolonged to 50 and 60 minutes in individual animals.

Platelets—The data from sixteen animals studied consecutively after nitrogen mustard administration are shown in Fig 2. The mean maximum decrease in the platelets per cubic millimeter had occurred by the fourth day after nitrogen mustard administration, and remained below normal values for *circa* seven days. The lowest mean platelet level (150,000 per cubic millimeter) did not parallel the high peak in the clotting time on the seventh day, but the return of the clotting time to normal limits paralleled the return of the platelets to normal values. Even more striking is the fact that the clotting time in practically all animals had increased prior to a significant reduction in platelet values. These facts are clearly illustrated in individual animals as is shown in Fig 3.

Heparin Tolerance—In general, the effect of nitrogen mustard on the heparin tolerance paralleled the effect on the clotting time. As the clotting time of the animal rose, a greater concentration of protamine sulfate was necessary to produce a clot in the heparin tolerance tubes in one hour. This is illustrated in Figs 3 and 6.

Fibrinogen and Calcium—Without exception fibrinogen was present in all plasma samples. The blood calcium determinations of the nitrogen mustard

Fig 2—Clotting time (1 c.c. blood) and platelet values in sixteen rabbits following the intra venous administration of 3 mg per kilogram of nitrogen mustard

Fig 3—Clotting time (1 c.c. blood) platelet values and heparin tolerance test (one hour readings) in one rabbit (0.33) following the administration of 3 mg per kilogram nitrogen mustard

treated animals with delayed clotting and an abnormal heparin tolerance test were within the normal range (13 to 14 mg per cent)

Prothrombin Time—As stated, blood for a prothrombin time determination was obtained simultaneously with blood for clotting time and heparin tolerance determinations in all control and mustard injected animals. In no instance was a prolonged prothrombin time observed in animals which had a prolonged clotting time or abnormal heparin tolerance test as a result of the nitrogen mustard intoxication.

Fig 4—Average clotting time (1 c.c. blood) and platelet values in sixteen rabbits after 800 r total-body X irradiation

Fig 5—Clotting time (1 c.c. blood) platelet values and heparin tolerance test (one hour results) in one rabbit (0762) after 800 r total-body X irradiation

Effect of X-Rays—Exposure to 800 r total-body X radiation produced results similar to those described following nitrogen mustard administration except that the prolonged clotting time persisted for a longer period of time and the platelets, which were reduced by the fifth day, remained reduced for a period of seven days or longer. Fig 4 is representative of this group.

of sixteen animals. The heparin tolerance test, clotting time, and platelet values of one animal following irradiation are shown in Fig 5. These results are representative of those animals which did not survive.

Prothrombin time remained unchanged in the animals exposed to 800 r X radiation. The blood calcium values likewise remained within normal limits and fibrinogen was present in all plasma samples.

Effect of Antiheparin Substances on the Prolonged Clotting Induced by Nitrogen Mustard or X Ray—The effect of intravenously administered toluidine blue or protamine sulfate on the clotting time of normal animals and animals with a nitrogen mustard induced prolongation in the clotting time

Fig 6—The effect of antiheparin substances (toluidine blue and protamine sulfate) on the prolonged clotting time (1 c.c. blood) platelet values and decreased heparin tolerance (three hour results) in a rabbit (0718) produced by the intravenous administration of 3 mg per kilo gram of nitrogen mustard.

was studied repeatedly in individual animals. Single doses of from 3 to 4 mg per kilogram of toluidine blue were administered either intracardially or intravenously (ear vein), and observations on the clotting time, heparin tolerance, and platelet values were made at two and twenty-four hours after injection. The same procedure with a dosage range of 2 to 3 mg per kilogram was followed when the effect of protamine sulfate was similarly investigated.

The effect of intravenous injections of toluidine blue and protamine sulfate on the whole blood clotting time and heparin tolerance test of an individual rabbit following 3 mg per kilogram of nitrogen mustard is shown in Fig 6. The intravenous injection of 2 mg of protamine reduced the clotting time from 48 to 8 minutes in two hours. The amount of protamine decreases

Fig 7A—The effect of toluidine blue on the prolonged clotting time (1 c.c. blood) platelet count and heparin tolerance (one-hour readings) in a rabbit (0780) following 800 r total-body X irradiation

Fig 7B—Effect of repeated doses of protamine sulfate on the prolonged clotting time platelet values and heparin tolerance in a rabbit (0761) following 800 r total body X irradiation

sary to produce a clot in the heparin tolerance test was reduced from 25 to 10 γ during the same period. The intravenous injection of 3 mg of toluidine blue per kilogram of body weight gave similar results in the same rabbit six days after the first injection of protamine when the clotting time was again prolonged. After the toluidine blue injection, the clotting time dropped from 65 minutes to 42 minutes in two hours, and then to 35 minutes in twenty-four hours. Another injection of 4 mg of toluidine blue reduced the clotting time to 22 minutes in two hours, after which the animal made an uneventful recovery.

No significant change was noted in the number of platelets per cubic millimeter following the injections of toluidine blue or protamine sulfate.

Without exception in the presence of a nitrogen mustard induced prolongation in the clotting time, the intravenous injection of toluidine blue in 3 or 4 mg per kilogram doses or of protamine sulfate in doses ranging from 15 to 25 mg per kilogram significantly reduced the clotting time. In some instances the clotting time was reduced to the normal range by two hours or significant reduction in the clotting time was produced by two hours but was not reduced to the normal range. In others, the clotting time was significantly reduced by two hours, reached the normal range twenty-four hours after injection of toluidine blue but by forty-eight hours was again prolonged.

In rabbits exposed to 800 r total body γ irradiation the effects of toluidine blue and protamine sulfate on the prolonged clotting time are shown in Figs 7A and 7B. Although the clotting time was reduced in rabbit number 0780 (Fig 7A) from 41 minutes to 18 minutes in two hours after the intravenous administration of 3 mg of toluidine blue per kilogram of body weight the effects on the heparin tolerance test were not remarkable. The following day the clotting time was again prolonged (30 minutes) and an increased amount of protamine was necessary to bind the heparin in the heparin tolerance test. Before another injection of toluidine blue could be administered the animal died. Occasionally as in this animal an abnormal heparin tolerance fails to revert to normal two hours after the intravenous administration of an antiheparin substance even though the clotting time was returned to normal or significantly reduced. By twenty-four hours after toluidine blue or protamine injection however the heparin tolerance was normal if the clotting time had returned to normal.

Animal number 0764 received protamine sulfate in 15 mg per kilogram amounts intravenously at 10 AM and 4 PM when the clotting time was 43 minutes and when 35 γ of protamine did not clot the blood in the heparin tolerance test. The following day when the clotting time was 34 minutes another injection of protamine (1 mg per kilogram) was given intravenously. Although the clotting time was reduced to 17 minutes in twenty-four hours after the last injection of the protamine sulfate the animal did not survive. It is likely that these animals died as a result of the cardiocentesis or from the general γ irradiation effects rather than from the protamine or toluidine blue injections.

DISCUSSION

A prolonged clotting time and an abnormal "heparin tolerance" were almost invariably produced in rabbits given a single intravenous dose of 3 mg per kilogram or more of nitrogen mustard (methyl-bis-(β -chloroethyl) amine hydrochloride). A similar effect was produced in rabbits after exposure to 800 r whole-body X radiation. The prolonged clotting time appeared by twenty-four hours in rabbits given nitrogen mustard, whereas significant prolongation in clotting time was not consistently observed until the second or third day after irradiation. Spontaneous recovery from this effect occurred earlier in the nitrogen mustard treated animals than in irradiated animals. The effects of a single injection (30 mg per kilogram) of nitrogen mustard on the cellular elements and hemoglobin of the peripheral blood and the histologic effect on the hemopoietic tissues are essentially comparable with those produced by 800 r whole-body X radiation. Recovery of the bone marrow and lymphatic tissue and return of the cellular constituents of the peripheral blood to normal values after doses of these two agents is more rapid in nitrogen mustard treated animals than in the irradiated animals.⁹ Since, however, these two agents are not strictly comparable in terms of selectivity and mechanism of action, one cannot expect the appearance of or recovery from largely identical biologic effects to be the same.

The mechanism of the prolonged clotting time and altered heparin tolerance, which appears after nitrogen mustard intoxication, is probably identical with that described by Allen and Jacobson² in the dog after exposure to lethal amounts of X radiation, namely an increase in a circulating heparin or heparin-like substance. This is substantiated by the facts that the prothrombin time, fibrinogen, and calcium levels were normal in the animals with a prolonged clotting time, no fibrinolysis was demonstrated, and antiheparin substances, such as toluidine blue and protamine, were capable of reversing to normal values or significantly reducing the prolonged clotting time for varying lengths of time. The recent report by Smith, Jacobson, and co-workers⁵ has shown that therapeutic doses of nitrogen mustard produced this same effect in the human being. It is of interest in this connection that the dose required to produce this clotting defect in the rabbit with regularity is about seven times the total dose usually used for therapeutic purposes in the human being.

In the original publication by Allen and Jacobson² it was pointed out that not infrequently a prolonged clotting time was observed in X-irradiated dogs before thrombocytopenia developed. In the rabbit, after intoxication with either nitrogen mustard or x-ray, the clotting time is almost always significantly increased prior to significant reduction in platelet values. On the other hand, the maximum increase in clotting time roughly parallels or occurs concomitantly with the maximum platelet decrease. Spontaneous recovery of both to normal levels occurs at practically the same time. Reversal of the clotting time and heparin tolerance to the normal range by the intravenous administration of toluidine blue or protamine sulfate did not significantly

alter the platelet level. These facts do not necessarily indicate, however, that platelets have no role in the production of this "syndrome".

The results of these experiments are interesting from the standpoint that a clotting defect is produced by nitrogen mustard which is similar to that produced by ionizing radiations. It seems likely that other chemical substances with the capacity to produce severe damage to the blood forming tissue may likewise produce a prolonged clotting time in which heparin or a heparin like substance is involved. It is an important fact that spontaneous recovery from this hemorrhagic syndrome produced by either nitrogen mustard or irradiation is possible. It is also significant that antiheparin substances are therapeutically effective in the treatment of this syndrome.

SUMMARY AND CONCLUSIONS

A prolonged clotting time is produced in rabbits by the intravenous administration of 3 or 4 mg of nitrogen mustard per kilogram of body weight. The same syndrome is produced in human beings after therapeutic doses of this drug. The amount of protamine necessary to produce clotting in the heparin tolerance test is increased in those rabbits that develop a prolonged clotting time.

The prolonged clotting time occurs in rabbits after a 3 mg per kilogram dose within twenty four hours after administration and persists for approximately twelve days. Spontaneous recovery occurs in surviving animals by the twelfth to fourteenth day. A maximum reduction in blood platelets occurs by the fourth day in rabbits receiving 3 mg per kilogram nitrogen mustard, with recovery by the twelfth to fourteenth day. Thus the clotting time is prolonged prior to significant platelet reduction. However, the period of platelet reduction (fourth through twelfth day after nitrogen mustard administration) roughly parallels the period in which maximum increase in the clotting time exists. Spontaneous recovery of the clotting defect and the return of platelet values to normal levels in the peripheral blood occur at a comparable time (*circa* fourteen days).

Animals which developed a prolonged clotting time had normal calcium and prothrombin values.*

The prolonged clotting time and decreased "heparin tolerance" are reversible with antiheparin substances. The anticoagulant present in the blood is probably heparin or a heparin like substance.

The clotting defect produced by nitrogen mustard resembles that produced by whole body X irradiation (800 r) in rabbits and is also reversible with antiheparin substances.

It is suggested that the potentially serious clotting defect may be produced by other agents producing toxic effects directly or indirectly on the blood forming tissue. This should be borne in mind since a method of treatment is available (antiheparin substances) which may make it possible to pass the critical period of potential hemorrhage until spontaneous recovery ensues.

* Since submission of the manuscript, quantitative fibrinogen determinations have been done on a few animals in which a prolonged clotting time was present after nitrogen mustard administration. In these animals the fibrinogen values were normal.

THE USE OF PLASMODIUM VIVAX PRESERVED BY FREEZING IN INDUCING MALARIA

GEORGE M SAUNDERS, M D DAVID W TALMAGE M D AND VIRGIL SCOTT M D
St Louis Mo

FEVER from induced malaria continues to be widely employed in the management of neurosyphilis, particularly in parenchymatous forms such as dementia paralytica and primary optic atrophy. A serious obstacle to the use of malaria has been the difficulty of maintaining a source of parasites. Even in metropolitan areas, cases of malaria naturally acquired or deliberately induced are frequently not available. This difficulty has increased since the introduction into syphilotherapy of penicillin. Milder forms of neurosyphilis are now treated effectively with this antibiotic alone, consequently treatment with induced fever is less frequently necessary and fewer cases of malaria are to be found. It may be troublesome and time consuming to obtain malarial blood from distant medical centers and unless shipment is rapid and delivery prompt the blood may be noninfectious by the time inoculation is accomplished. Since malarial parasites remain viable at room temperature for three to five days at most, a simple effective method for their preservation for longer periods has practical value.

By a method of quick freezing of malarial blood and storage at low temperatures, we have had available a supply of *Plasmodium vivax* parasites which has been used successfully during the past year to induce malaria in approximately forty patients in hospitals in the St. Louis area.

A preliminary report¹ briefly outlined the method used and cited successful inoculations in six patients, three of which were described in detail. It is the purpose of the present paper to record the experience with a larger series of cases.

It is well known that many infectious agents bacterial and viral can be maintained in the frozen state. As summarized in our previous communication several types of pathogenic protozoa, including those of avian and monkey malaria have been similarly preserved.¹ The only previously recorded attempt at preserving human plasmodia was that of Coggeshall² who was unsuccessful using a method which involved rapid freezing at -72° to -80° C followed by slow thawing. The procedure employed in the present study is fundamentally similar except that thawing has been effected rapidly rather than slowly.

ORIGIN OF PARENT STRAINS

H K Strain—This strain was isolated April 8 1947 from a 29 year old veteran during an acute episode of relapsing malaria. H K. had been exposed in the Southwest Pacific area, New Guinea and the Philippines, from June 1944 to December 1945. Throughout this time while on routine quinacrine suppression no clinical attacks of malaria occurred.

From the Departments of Preventive Medicine and Internal Medicine Washington University and the Syphilis Clinic of the Washington University Clinics.

The work described in this report was supported by a grant from the National Institute of Health.

Received for publication Sept 8 1948

Suppressive therapy was stopped in December, 1945, when he returned to the United States, a few weeks later he suffered his first acute attack of malaria which was followed by repeated relapses, about ten in all, between February, 1946, and April, 1948. Blood first was drawn for preservation on April 8, 1947, after three paroxysms, the last one having occurred four to six hours before venipuncture. Blood films showed numerous amoeboid and younger forms of *P. vivax* with a parasite density of about 10,000 per mm³. During the course of the next year, partly through oversight and the more frequent use of another preserved strain of *P. vivax*, the H K strain was lost, but was recovered in April, 1948, when H K again suffered a relapse. Blood drawn a few hours after a shaking chill when the patient's temperature was 39.2° C showed many young ring forms, about 20,000 per mm³.

N Y Strain—This strain was isolated June 13, 1947, from a 29 year old war veteran on the first day of a relapse. While serving in the Philippines during 1944-1945, N Y suffered his initial attack of malaria. Since discharge from the Army he had been having relapses every two to three months. At the time of blood withdrawal numerous young ring forms of *P. vivax* were present on smear, a parasite count indicated about 5,000 per mm³.

METHOD OF PRESERVATION*

Blood from malarial donors was prevented from clotting by the use of sodium citrate or by defibrination with glass beads. Citrate was employed in a 4 per cent solution in a ratio of 5 parts of blood to 1 part of sodium citrate, giving a final concentration of less than 1 per cent of the salt. A part of the citrate was drawn into the collecting syringe in order to eliminate possible coagulation in the syringe, then the required amount of blood was drawn and the contents of the syringe were added to a flask of 125 ml capacity containing the remainder of the citrate. Defibrination was accomplished by adding the blood to a flask containing a layer of glass beads and shaking or rotating the contents gently until the fibrin collected in a mass about the beads.

After citration or defibrination the blood was transferred in 2 to 4 ml amounts to thin walled glass ampules, about 15 by 80 mm in size, and the ampules were sealed by flaming. The ampules were then immersed in a previously prepared freezing solution consisting of ethyl alcohol and dry ice at a temperature of -70° to -80° C. Ampules were immersed individually while being rotated rapidly in order to disperse the contained citrated blood into a thin film on the inner surface of the ampule. Freezing was thus accomplished in the course of a few seconds. After remaining in the freezing mixture approximately ten minutes, the ampules were transferred to a dry ice box for storage at -70° C. A commercial home freezer with a specially constructed insulated inner cabinet containing a central space for storage of ampules and compartments at the ends for dry ice has proved satisfactory for this purpose. The entire process, from venipuncture to storage, was completed as rapidly as possible, usually requiring no longer than thirty to forty five minutes. Aseptic precautions were observed throughout.

Ampules were removed as needed, rapidly thawed at the bedside by immersion in a water bath at 40° C, and the fluid immediately was injected intravenously into the recipient. The usual inoculum consisted of the contents of two or three ampules, a volume of 4 to 10 ml, although as little as 2 ml has been used successfully.

TRANSFER OF STRAINS

Following the development of clinical malaria, patients were bled after varying numbers of paroxysms and during various phases of the life cycle of the parasite, and the freezing and storage process was repeated. Thus, the parent strains were maintained by serial passage from one patient to another. Inoculations were performed uniformly with material which had been frozen and resort to direct transfer was not necessary.

*Although the method described includes minor modifications adopted during the course of the study the procedure has remained essentially unchanged.

DESCRIPTION OF SUBJECTS

Since the beginning of the experiment a little more than a year ago a total of fifty four subjects has been inoculated with preserved *P vivax* blood one subject being inoculated twice, for a total of fifty five inoculations. All subjects were patients with neurosyphilis in whom malaria was being induced for therapeutic purposes. All were adults forty eight were men and six were women, all were white except one Negro and one Mexican of mixed blood. The racial selection was premeditated since it is well known that Negroes are frequently immune to vivax malaria. The patients were hospitalized in ten different hospitals in the St. Louis area.

RESULTS

Results of inoculation have been classed as successes failures incomplete data and lost to observation, according to the following criteria. An inoculation was considered a success when it was followed by oral temperatures of 37.8° C or more on at least one occasion forty eight hours or more following inoculation in addition to the demonstration of malarial parasites in thick or thin blood preparations. In successful cases the incubation period was calculated as the time in days from inoculation to the first febrile elevation.

Cases were officially classed as failures when parasites were not found in the blood during the period from about six days to four or five weeks after inoculation. However, two patients who had irregular low grade fever on the tenth to fourteenth postinoculation days without parasites being demonstrated subsequently developed typical malarial paroxysms with demonstrable parasites one forty five days and the other seventy eight days after inoculation. Hence it seems likely that some of the patients who were classed as failures after four to six weeks and who were then lost from observation or given antimalarial therapy might have developed malaria. Cases classed as incomplete include those patients whose postinoculation period is currently less than four weeks without clinical or laboratory evidence of malaria and two patients who were discharged from hospitals less than three weeks after inoculation who developed chills and fever at home, recorded temperatures exceeding 39° C and who promptly became afebrile following antimalarial therapy blood smears not being available for examination during the posthospital period. In the two cases lost to observation the patients left the hospital less than a week following inoculation and subsequent observations are lacking.

Of the fifty five inoculations there are at present forty six cases with data adequate to classify as success or failures. Table I shows that forty or 87 per cent of the forty six, developed malaria, and six or 13 per cent were classed as failures. These six failed to develop malaria clinically and parasites were never demonstrated by smear over observation periods ranging from thirty four to ninety days.

TABLE I. RESULTS OF INOCULATION OF *P. VIVAX* STRAINS PRESERVED BY FREEZING

RESULT	STRAIN N. Y.	STRAIN H. K.	TOTAL
Successes	34	6	40
Failures	4	—	4
Total	38	6	46
Incomplete	1	5	6
Lost	2	0	2
Total	41	11	52

Sufficient information relative to possible strain differences has not been accumulated thus far. Among the cases for which we have adequate data, of thirty-eight inoculations performed with N Y strain, thirty, or 90 per cent, have been successful, six, or 75 per cent, of eight inoculated with H K strain developed malaria.

In considering causes of failure other than technical error, three factors deserve mention—previous malarial infection, race, and the inadvertent suppression of the malaria by drugs possessing antimalarial activity. Whether any of the six known failures had suffered previously from naturally acquired malaria and might, therefore, have been immune is not definitely known. Two of these patients, so demented that historical information on this point could not be obtained, had lived in malarious regions. One was a Greek who had lived in his native country for an eighteen-year period, the other was a Mexican who was also probably part Negro. A third patient, classified as a failure after forty-five days of observation following an initial inoculation with the H K strain, subsequently was reinoculated successfully with the N Y strain, the incubation period (sixteen days) being within the usual range. In this patient the original inoculation was probably faulty since it seems less likely that strain differences would have influenced the result. Failure may be explained in the case of the one Negro subject on the basis of race resistance.

None of the forty who developed malaria are known to have had the naturally acquired disease, but one had been previously inoculated (unsuccessfully) with fresh blood containing quarian parasites.

In reference to antimalarial drugs, it is well known, although perhaps not widely recognized, that both the sulfonamides and the heavy metal antisypilitic agents,* including the arsenicals and bismuth, may abort or suppress infection with malarial parasites. The same effect may be produced by even minute doses of quinine comparable to those contained in some of the commonly used "tonics." To our knowledge, none of the failures were related to the administration of these drugs, although several of these patients were not under our own observation. It may be of interest to refer to one patient who developed severe convulsive seizures a few days after inoculation and a day or two after penicillin therapy was instituted. To control the convulsions the patient was given regular doses of phenobarbital, and Dilantin sodium, 90 mg three times a day. It was felt that his failure to develop malaria might have been due to some suppressive action of the barbiturates or Dilantin since it is known that many types of complex organic compounds may act as antimalarials. To test the supposition that Dilantin might act in this manner, one patient in whom it was desired to terminate malaria was given Dilantin sodium, 90 mg three times a day for a period of four days. He suffered a regular malarial paroxysm on the first day of Dilantin treatment but was afebrile subsequently for five days, during which malaria parasites were not found in blood smears. At this time the patient was given a course of chloroquine to make sure the malarial infection was terminated. In another patient, similar doses of Dilantin for three days failed to have any apparent effect upon the malaria, and because of his critical condition the patient was treated with chloroquine to end the attack.

*But not penicillin

In attempting to analyze the results of inoculation there are a number of variable factors, some of which may be controlled and measured with reasonable accuracy, while others are beyond control and cannot be measured with present methods. The measurable, controllable factors include parasite strains, the number of parasites in the inoculum before freezing, the stage of development of the parasites, the method of preventing clotting, the speed of freezing and thawing, the storage temperatures, and the duration of preservation. The uncontrollable, incalculable factors include the host resistance whether due to previous malaria or other factors including race.

Parasite Strains—The differences in results of inoculations with the two strains used in this study including the proportion of successes to failures and the incubation period in the successes, are too small to be of significance.

The Size of Inoculum—It might logically be assumed that few parasites might fail to produce malaria, or produce it only after a prolonged incubation period, and that a large number of parasites would produce malaria more consistently and with a relatively short incubation period. In most instances a rough parasite count was made on donor's blood by relating the number of parasites found in stained smears to the number of leucocytes seen and to the total leucocyte count. But, although we can thus estimate the number of parasites in a given quantity of blood before freezing, it has not been possible to determine how many survive the freezing, thawing, and storing.

There is no evidence that the total number of parasites in the inoculum before freezing accounted for success or failure in producing malaria in the host. In the six cases classed as failures the number of parasites was greater on the average than in the cases classed as successes and the blood had been preserved for shorter periods of time. Furthermore when the successes are grouped according to number of parasites in the inoculum as shown in Table II, there is no evidence that the incubation period was altered significantly by increasing the number of parasites. The length of time the parasites were stored was essentially comparable in all groups except the fourth in which there was a much longer average storage time and a slightly shorter incubation period.

TABLE II THE SIZE OF INOCULUM, THE LENGTH OF STORAGE OF PARASITES AND THE INCUBATION PERIOD IN CASES OF SUCCESSFUL INOCULATION

SIZE OF INOCULUM NUMBER OF PARASITES IN MILLIONS (PER MM ³)	TIME FROZEN IN DAYS		INCUBATION PERIOD IN DAYS		NUMBER OF CASES
	MEAN	EXTREMES	MEAN	EXTREMES	
9.19	31.7	10-102	12.8	9-14	7
21.40	31.1	6-85	12.6	10-22	14
41.69	54.4	6-166	11.3	7-16	12
100.137	26.5	3-59	15.0	12-20	4

The Stage of Development of Parasites—It is possible that the resistance of parasites to freezing and thawing and prolonged storage at low temperatures might vary with their age, size, and complexity of structure that is, with the stage of development. As a working hypothesis it was assumed that the merozoites, or very young trophozoites, might be the most resistant, and the mature

TABLE III THE STAGE OF DEVELOPMENT OF PARASITES RELATED TO THE INCUBATION PERIOD

STAGE OF DEVELOPMENT OF PARASITES IN INOCULUM	TIME INCUBATION PERIOD IN DAYS					TIME FROZEN IN DAYS		SIZE OF INOCU- MUM, MILLIONS OF PARASITES PER MM. ³	NUMBER OF CASES
	MEAN	MEDIAN	MODE	EXTREMES		MEAN	EXTREMES		
Young trophozoites	11.9 ± 3.74	11.5	10.7	6.22		44.0	6.131	9.100	20
Mature trophozoites	13.9 ± 2.77	14.0	14.2	10.20		18.0	3.47	9.137	8
Schizonts	12.3 ± 2.37	12.0	11.4	10.16		42.9	9.166	19.46	9

trophozoites and schizonts, the least resistant. If that hypothesis were correct then we would expect more successes and shorter incubation periods when using the younger forms. We have tried to draw blood from donors at times in relation to the developmental cycle to provide young, half grown or mature forms of the parasites. However, since merozoites are beginning to be liberated probably hours before the mass disruption of schizonts, both young and old forms of parasites may be present in considerable numbers near the end of the cycle and differences in results might be expected to be less from samples taken early and late than from those taken early and mid way in the cycle.

It is not possible to decide whether age of parasites had any effect on the proportion of successes to failures because the numbers are too few. Successes and failures both followed inoculation of young, middle aged or old parasites. When successes alone are considered there is suggestive evidence that the incubation period was shorter when the inoculum contained a majority of young ring forms than when the majority were mature trophozoites. This is shown in Table III, which indicates that when young ring forms predominated the incubation periods were grouped around eleven days, when mature trophozoites predominated, around fourteen days, and when schizonts predominated with some young trophozoites the incubation periods were grouped around twelve days. In other respects the groups are fairly comparable except that the average time frozen was much shorter in the mature trophozoite group.

It is always hazardous to draw conclusions from small differences which may exist between small groups, but apparently there is a significant prolongation of incubation period in the mature over the young trophozoite groups. The difference between the means is 2 ± 0.737 , the difference being nearly three times the standard error. The significance of the difference is further borne out by a comparison of results following inoculation of one group of seven patients with blood from donor M₁ with another group of four patients inoculated with blood from H₀. The size of inoculum and duration of preservation were essentially equal and the blood had been citrated in both cases. Blood from M₁ showed parasites approximately forty hours old, schizonts while that from H₀ taken just at the time of the paroxysm showed a majority of parasites to be very small ring forms with a number of mature schizonts. In the M₁ group the incubation period averaged 12.7 days with a range of ten to sixteen days while in the H₀ group the incubation period averaged 7.7 days with a range of six to ten days.

Anticoagulation—Citrated blood was used in thirty two cases with successes resulting in 27 or 84 per cent and defibrinated in 14 cases with 13 or 93 per cent resulting in malaria. This is not a significant difference. In the cases in which malaria developed there was no apparent significant difference in incubation periods in the two groups which were comparable in other ways.

The speed of freezing and thawing was as nearly identical as possible in all cases and the conditions of storage were the same in all.

The Length of Period of Storage—There is no evidence that the length of time the parasites are kept frozen affects the final results of inoculation. In comparing successful with unsuccessful inoculations it is found that failures

followed freezing periods ranging from 11 to 137 days, and successes followed freezing periods ranging from 3 to as long as 166 days. Other factors in the two groups were essentially comparable. In considering only successful inoculations, Table IV indicates that the incubation period does not change as the duration of freezing increases.

TABLE IV THE LENGTH OF STORAGE OF PARASITES IN RELATION TO THE INCUBATION PERIOD AND SIZE OF INOCULUM

STORAGE PERIOD IN DAYS	INCUBATION PERIOD IN DAYS		SIZE OF INOCULUM, PARASITE COUNT IN MILLIONS PER MM ³	NUMBER OF CASES
	MEAN	EXTREMES	EXTREMES	
3 10	12.2	9 16	9 64	6
11 20	13.2	10 20	9 137	11
22 28	12.0	10 16	13 225	7
37 59	12.1	6 17	13 100	7
70 166	12.1	8 22	17 69	7
3 166	12.4	6 22	9 225	38

Incubation Period—In thirty-eight patients who developed malaria, the incubation period, when it could be accurately determined, varied between six and twenty-two days, the mean being 12.4 days. This would seem to be somewhat prolonged over that following the direct transfer method. Moore³ stated that with the latter using an inoculum of 1 to 10 ml. the average incubation period is three to eight days. We have had only one opportunity to draw a comparison between the two methods. Using direct transfer the incubation period in one recipient was forty hours, with the same blood preserved and inoculated into a different patient, 10 days. It seems likely that the destruction of many plasmodia as a result of the freezing and thawing process, rather than a host factor, was responsible for the prolongation of the incubation period.

The success or failure of attempts to produce malaria in equally susceptible subjects with blood preserved by freezing and the incubation period must depend upon the number of viable parasites surviving. Although available data are insufficient, we have the impression that one important factor in determining the number of parasites surviving is the stage of development, and that merozoites or young trophozoites are more resistant than older forms.

Evidence also has been obtained that infectiousness is not affected adversely by repeated freezing. One strain has been passed serially through six patients, the preservation process being repeated each time, without a significant change in incubation period. Repeated freezing and thawing of the same specimen of blood have not been attempted.

Reactions to Inoculum—The preservation process results in almost complete hemolysis of the red blood cells, smears after thawing show only an occasional intact cell. The staining properties of the malarial parasites also appear to be affected for, after thawing, the latter are poorly stained by either Wright's or Giemsa's method. Despite these rather marked alterations resulting from the preservation process, no untoward effects directly attributable to the inoculum have been observed following intravenous injection of the relatively small amounts (4 to 10 ml.) employed.

Clinical Course of Malaria—The clinical course of the disease resulting from inoculations with preserved parasites has in no way differed from that seen following the direct inoculation of whole blood. Striking individual differences in the severity of the disease have been observed, some patients exhibiting a low parasitemia and tolerating the infection well. Others have had fulminating infections, high parasite indices with red blood cells containing as many as three to five parasites, terminating in peripheral circulatory collapse which necessitated interruption of treatment. This individual variation to infection is believed to be related to host rather than to parasite factors. There have been no fatalities in this series of cases.

CONCLUSIONS

1 Preservation of viable parasites of *vivax* malaria for many months by a simple method of quick freezing, storage at low temperature (-70°), and quick thawing has provided a constantly available supply of parasites in the St. Louis area during the past year.

2 Among forty-six subjects inoculated with preserved blood, forty or 87 per cent, subsequently developed malaria.

3 The incubation period in those cases of malaria in which an accurate determination was possible averaged 12.4 days, ranging from six to twenty-two days. Malaria was first proved in two additional subjects, forty-five and seventy-eight days after inoculation, although both had slight temperature elevations at ten to fourteen days at which time parasites were not found in blood films.

4 The incubation period probably is directly related to the number of parasites surviving preservation, which in turn appears to be inversely related to the age of parasites; younger forms of parasites are apparently more resistant to freezing and thawing.

5 The clinical course of malaria does not appear to differ in any way from that following infection with fresh parasitized blood.

The authors wish to thank Dr. Louis Kohler, Superintendent of the Missouri State Hospital, and especially Dr. Leopold Hofstatter of the same institution, and Dr. Alfred K. Baur of Jefferson Barracks Hospital for their assistance in providing subjects for inoculation.

LABORATORY METHODS

SPUTUM CELL STUDY FOR PULMONARY CARCINOMA AS A ROUTINE LABORATORY TEST

BURTON A. SHATZ, M.D., MARTIN BERGMANN, M.D., AND S. H. GRAY, M.D.
St. Louis, Mo

ALTHOUGH the examination of sputum for neoplastic cells as an aid in the early diagnosis of carcinoma of the lung has become well established,^{4, 11} it is still not being carried out in most laboratories as a routine procedure. The reasons for this hesitancy are understandable. Fear of the harm that might be wrought by a false positive diagnosis, the feeling that specialized cytologic knowledge is required, and the long time frequently necessary for the adequate study of a single case have acted as deterrents. Thus, while there are at present a few laboratories in which this technique for early diagnosis of cancer is being applied very successfully, it is not yet available to most physicians.

To stimulate more widespread use of this valuable diagnostic aid, perhaps a more practical approach to this problem is needed. It has been our experience that the great majority of positive sputum diagnoses are based on cells which have easily recognizable neoplastic characteristics. It was suspected that by confining positive diagnoses only to the relatively obvious cases, the sputum examination might prove to be more adaptable to routine use in a clinical laboratory without fear of false positive diagnoses, and at the same time retain a useful degree of acuracy.

To test this suspicion, a group of forty consecutive cases of proved carcinoma of the lung, in which sputum examinations were done, were analyzed. It was found that in twenty-nine cases (72 per cent) the sputum contained obviously malignant cells. While this percentage of positive results is lower than that reported by some authors,^{4, 6} it is still high enough to be of distinct clinical value. Thus, in seven of the twenty-nine cases in which we demonstrated neoplastic cells in the sputum, bronchoscopy had been entirely negative, and histologic proof of the suspected presence of a lung tumor could not be secured by any other means short of exploratory thoracotomy. It would appear that by restricting positive diagnoses only to those patients whose sputa contain easily identifiable malignant cells, and by reporting all others as negative, the sputum examination should become practical for more general adoption. This paper outlines the technique of preparing sputum slides, describes and illustrates the cellular elements encountered, and sets forth the characteristics of the obviously malignant cells.

TECHNIQUE

The technique has been described in other publications¹⁰ but certain points bear emphasis. The proper collection of the specimen is one of the most important steps in the sputum examination. Due care exerted in this part of the procedure will be rewarded by noticeably better results and will save the examiner a great deal of time spent in unfruitful search of specimens containing almost no bronchial secretion. The patient must be instructed to cough up material from the tracheobronchial tree and must not be allowed to present the examiner with saliva or nasopharyngeal secretions as a specimen. Material from the patient's bedside sputum cup is usually not satisfactory, due to the dilution of whatever bronchial secretions there are with a relatively large amount of saliva. We have found it advisable to have a well-instructed technician or nurse obtain the specimen directly from the patient.

Storage—It is best to smear and fix the specimen as soon after collection as possible. However, when necessary a specimen may be allowed to remain in the refrigerator for four to six hours without appreciable deterioration.

Preparation of Slides—The specimen is poured into a Petri dish placed on a black background. An effort is made to find small fragments of tissue and blood tinged material. Samples of the various components of the sputum are selected and placed on a glass slide. A fairly thin and uniform film is obtained by smearing the material with a second glass slide. Ordinarily five slides are prepared from each specimen.

Fixation—Fixation of the film is accomplished by immersion for at least thirty minutes in a mixture of equal parts of ether and 95 per cent alcohol. It is important for the preservation of cellular details that no drying of the film be allowed to occur before it is fixed. The slides should be placed in the fixative while still wet.

Staining—The stain employed is hematoxylin and eosin. This stain presents two important advantages over other stains that have been advocated for use in this work. First it allows the staining of sputum slides to be carried out simultaneously and by the same technique as other routine slides. Second it relieves the pathologist of the necessity of familiarizing himself with a new stain. From the ether alcohol mixture the sputum slides are transferred to 95 per cent alcohol for one minute and from then on are handled as are ordinary tissue sections. In our laboratory this consists of the following:

- 1 Water for one minute
- 2 Harris hematoxylin for one minute
- 3 Water for one minute
- 4 Dip in acid alcohol
- 5 Water for one half minute
- 6 Ammonia water till blue
- 7 Water for one half minute
- 8 One half per cent aqueous eosin for two minutes
- 9 Dip in water
- 10 Dip in increasing concentrations of alcohol to absolute alcohol
- 11 Beechwood creosote for five minutes
- 12 Xylol five minutes

The slides are then coverslipped with the use of Clarite. The preparation of the slides, fixation and staining, can easily be handled by a technician. The examination of the slide consists of scanning with the low power objective using a mechanical stage so that all parts of the preparation are seen. Suspicious elements are studied with the high dry objective.

NORMAL CELLS IN SPUTUM

All sputum specimens, regardless of the underlying pulmonary disease contain normal cells which can be classified according to their place of origin.

nuclei as to render adequate study difficult and to make it impossible to appreciate hyperchromasia, because all the nuclei, benign or malignant, will appear dark blue. One of the important criteria of malignancy is thus lost.

Another possible source of error may be the presence of degenerating normal cells. The changes brought about by this process include hyperchromasia and swelling of the nucleus, vacuolization of the cytoplasm, and changes in size and shape of the cell. Degenerating normal cells may thus assume what appear to be characteristics of malignancy. But careful observation will disclose loss of distinct cellular and nuclear outlines and loss of nuclear detail. Frequently, in the close vicinity one finds similar but better preserved benign cells, and others which are obviously and more completely degenerated. Occasionally macrophages which have no visible ingested material in their cytoplasm and whose nuclei are rather prominent are encountered. Such cells may simulate undifferentiated neoplastic cells, or, if they contain vacuoles, cells arising from adenocarcinoma. However, phagocytes occur only as individual cells and are not hyperchromatic, and similar cells with ingested material can usually be found in the immediate vicinity.

In chronic infectious diseases the normal bronchial epithelium may undergo squamous metaplasia (Plate I, 7). Fragments of the metaplastic epithelium are frequently exfoliated into the sputum and may resemble bits of well differentiated squamous carcinoma. However, these cells are arranged in an orderly fashion, have a definite polarity, and usually do not contain visible nuclei. As a result of degeneration, they may show both hyperchromasia and variation in size and shape of the nuclei. However, the cause of these characteristics becomes evident when one notes the loss of nuclear structure, distinct nuclear outline, and vacuolization of the cytoplasm.

Occasionally one is tempted to make a positive diagnosis on the basis of one or two single cells which have all the characteristics of malignancy. It is wise in such instances to withhold the final diagnosis until further specimens can be examined. In almost every case one will eventually find either numerous other similar cells or small fragments of tumor tissue. It has been shown that the examination of three separate sputum specimens will yield about 96 per cent of the positive diagnoses.¹ However, if the clinical history and roentgenographic studies strongly indicate malignancy, and especially when bronchoscopic biopsy is impossible, as in upper lobe lesions,¹ it is often desirable and worth while to repeat the examination several more times.

The diagnosis given to the clinician should be concise and explicit. We feel that the grouping of cells as to the probability of malignancy is confusing and even dangerous. Unless the pathologist is absolutely certain that carcinoma cells are present in the sputum, he should render a negative report. Care should be taken to advise the clinician as to the significance of positive and negative reports. The presence of cancer cells in the sputum is not a *priori* evidence of primary bronchogenic carcinoma. The cells may arise from carcinomas of the mouth, pharynx, nasopharynx, larynx, esophagus, trachea, or from pulmonary metastases, and in such instances cannot be differentiated from cells of primary bronchogenic neoplasms. Above all, one must be aware of the fact that failure

Cells From the Blood—The erythrocytes and leucocytes encountered in the sputum are as easily identifiable as in the usual tissue sections. Occasionally, when the sputum is purulent, the number of leucocytes is so great as to obscure the other cellular elements. In these instances it has been our policy to recommend a course of penicillin therapy to reduce the number of inflammatory cells and thereby facilitate proper sputum examination.

Cells From the Mouth and Pharynx—(Plate I, 1) These cells arise from squamous epithelium and are large and polygonal in shape. They contain an abundant amount of pale pink cytoplasm, with small centrally located nuclei. The nucleus is usually light blue, round to oval in shape, and surrounded by a distinct nuclear membrane. It has a finely granular chromatin network and may have a small distinct nucleolus. The cytoplasm may contain numerous invading bacteria. These squamous epithelial cells may occur singly or in sheets. The number of these cells present is a good index of the amount of saliva contained in the sputum. Their identification offers no difficulty.

Cells From the Epithelium of the Tracheobronchial Tree—(Plate I, 2 and 3) The tall ciliated columnar cells which line the trachea and bronchi are frequently present in the sputum and may occur singly or in clumps. The basal end may be drawn out into a long filamentous process. The nucleus is basally located, homogeneous in appearance, and stains deep blue. As many as three nuclei have been observed in a single cell. When these columnar cells occur singly and are not influenced by the presence of surrounding cells, they may assume a spherical shape. The ciliated border can be made more distinct by decreasing the aperture of the substage condenser. Goblet cells may be seen in the sputum. They can be recognized by the presence of a large mucigen droplet in the distal part of the cell, as seen in Plate I, 3.

Macrophages—(Plate I, 4, 5, 6) These are large round cells which may occur singly or as clusters of individual cells and are found in almost all sputa. They contain moderate-sized nuclei and abundant cytoplasm. The nuclei may be round, oval, or bilobed and usually have small nucleoli. However, at times the nucleolus is quite prominent. The chromatin is rather evenly distributed throughout the nucleus. Occasionally multinucleated giant macrophages are seen. The cytoplasm may be clear or may contain a variety of ingested particles and vacuoles. The blood pigment-containing cells (*heart failure cells*) have been found to be associated not only with chronic passive congestion of the lungs, but may also be found in a variety of conditions, especially those in which hemoptysis has occurred.

NEOPLASTIC CELLS

There are certain characteristics which most cancer cells have in common, regardless of the type of tumor from which they arise. These are as follows: (1) Neoplastic cells tend to occur in groups or tumor fragments. (2) Marked hyperchromasia of the entire cell is an outstanding characteristic and serves to make the malignant cells conspicuous even under low power magnification. (3) There is complete loss of polarity in the arrangement of neoplastic cells in a tumor fragment. (4) There usually is marked variation in the size and shape of malignant cells and their nuclei in any one tumor. (5) The nuclei of tumor

cells are generally large relative to the size of the cell. Multiple nuclei are not uncommon. (6) The nucleoli are large, distinct, often multiple, and may take a pink stain in contrast to the dark blue color of the nuclei. (7) Malignant cells may be phagocytic and it is not unusual to find one malignant cell ingested by another (Plate IV, 18). (8) Neoplastic cells may contain large, deep blue cytoplasmic bodies, which are known as bird's eye inclusions of Leyden (Plate IV, 20). The nature of these bodies has not been established, but it is thought that they probably arise from the multiplication of centrosomes, or that they are retained secretory products of the cell.³ The neoplastic cells in the sputum fall into two major categories: undifferentiated and classifiable.

1 *Undifferentiated Cells*—(Plate II, 9) These are tumor cells which possess only the described general characteristics. They arise from a totally undifferentiated tumor or from undifferentiated portions known to occur commonly in squamous carcinoma, adenocarcinoma and small cell carcinoma. Therefore undifferentiated neoplastic cells in the sputum may or may not reflect the predominating histologic character of a tumor. Conversely, a histologically differentiated tumor can give rise to both undifferentiated and classifiable elements in the sputum.

2 *Classifiable Cells*—These cells, in addition to the general characteristics of neoplastic cells, have certain distinguishing features which allow one to classify them as to the type of tumor from which they arise. (a) Squamous carcinoma cells (Plate II, 10, and Plate III, 11, 12). The squamous carcinoma cells tend to be elongated in shape. The nuclei are usually oval to spindle shaped, but may be round and have a dense coarsely granular chromatin structure. Nucleoli may be single or multiple and are usually very prominent, large and pink staining. The two characteristics that are diagnostic of this type of tumor are leucatinization of the cytoplasm which imparts to it a deep pink to red color, and the arrangement of the tumor cells in whorls. True epithelial pearls are not uncommon. (b) Adenocarcinoma cells (Plate III, 13, 14). Cells of this type are usually rather large and round or oval in shape. The nuclei are round, frequently multiple and commonly contain one or more small discrete nucleoli. Occasionally single large nucleoli are seen. The cytoplasm is usually abundant and several small or one or two large clear droplets of secretion are present. Secretory vacuoles are the only valid criterion for the diagnosis of adenocarcinoma unless one finds malignant cells forming true acini. This arrangement, however, is quite rare. (c) Small cell carcinoma (Plate III, 15). Small cell carcinoma cells are the smallest of the malignant cells in the sputum. They are round or elongated in shape and of fairly uniform size. The nucleus fills the cell almost completely so that only a narrow rim of cytoplasm is detectable. The nucleus is finely granular, moderate-sized, single nucleoli are the rule. To the untrained eye these cells resemble large lymphocytes except that they occur as fragments of tissue.

DISCUSSION

In applying the described criteria for malignant cells to the examination of sputum, one must be aware of certain pitfalls which may cause erroneous diagnoses. Overstaining with hematoxylin may so obscure the structure of the

nuclei as to render adequate study difficult and to make it impossible to appreciate hyperchromasia, because all the nuclei, benign or malignant, will appear dark blue. One of the important criteria of malignancy is thus lost.

Another possible source of error may be the presence of degenerating normal cells. The changes brought about by this process include hyperchromasia and swelling of the nucleus, vacuolization of the cytoplasm, and changes in size and shape of the cell. Degenerating normal cells may thus assume what appear to be characteristics of malignancy. But careful observation will disclose loss of distinct cellular and nuclear outlines and loss of nuclear detail. Frequently, in the close vicinity one finds similar but better preserved benign cells, and others which are obviously and more completely degenerated. Occasionally macrophages which have no visible ingested material in their cytoplasm and whose nuclei are rather prominent are encountered. Such cells may simulate undifferentiated neoplastic cells, or, if they contain vacuoles, cells arising from adenocarcinoma. However, phagocytes occur only as individual cells and are not hyperchromatic, and similar cells with ingested material can usually be found in the immediate vicinity.

In chronic infectious diseases the normal bronchial epithelium may undergo squamous metaplasia (Plate I, 7). Fragments of the metaplastic epithelium are frequently exfoliated into the sputum and may resemble bits of well differentiated squamous carcinoma. However, these cells are arranged in an orderly fashion, have a definite polarity, and usually do not contain visible nuclei. As a result of degeneration, they may show both hyperchromasia and variation in size and shape of the nuclei. However, the cause of these characteristics becomes evident when one notes the loss of nuclear structure, distinct nuclear outline, and vacuolization of the cytoplasm.

Occasionally, one is tempted to make a positive diagnosis on the basis of one or two single cells which have all the characteristics of malignancy. It is wise in such instances to withhold the final diagnosis until further specimens can be examined. In almost every case one will eventually find either numerous other similar cells or small fragments of tumor tissue. It has been shown that the examination of three separate sputum specimens will yield about 96 per cent of the positive diagnoses.⁹ However, if the clinical history and roentgenographic studies strongly indicate malignancy, and especially when bronchoscopic biopsy is impossible, as in upper lobe lesions,¹ it is often desirable and worth while to repeat the examination several more times.

The diagnosis given to the clinician should be concise and explicit. We feel that the grouping of cells as to the probability of malignancy is confusing and even dangerous. Unless the pathologist is absolutely certain that carcinoma cells are present in the sputum, he should render a negative report. Care should be taken to advise the clinician as to the significance of positive and negative reports. to find malignant cells in the sputum does not rule out carcinoma and should be disregarded if the weight of other clinical or radiologic evidence favors this diagnosis

CONCLUSION

Easily recognizable malignant cells occur in the sputa of more than 70 per cent of cases of pulmonary cancer. When one restricts positive diagnoses to these comparatively obvious cells the danger of false positive diagnoses is reduced to a minimum while at the same time the test retains a good degree of accuracy. With the realization of these facts sputum examination becomes more suitable for widespread adoption as a routine laboratory procedure.

A MICROADAPTER FOR THE EVELYN MACROCOLORIMETER

ESTHER F. FREIER, B.S., AND EVREL A. LARSON, M.D., PH.D.
MINNEAPOLIS, MINN.

THE Evelyn macrocolorimeter¹ requires the use of a minimum volume of 6 c.c. of solution in order to obtain a satisfactory colorimetric reading. It would be advantageous in some clinical procedures, such as the Evans blue dye blood volume method, to obtain a reading on a much smaller volume. The Evelyn microcolorimeter,² which allows colorimetric readings with volumes of solution ranging from 0.1 to 2.0 c.c. is technically difficult to operate, therefore, its application to routine laboratory procedures is limited.

In order to obviate the inherent difficulties of the Evelyn microcolorimeter, the microadapter described here was designed to permit readings on volumes as low as 1 c.c. with the Evelyn macrocolorimeter. Flat-bottomed microcolorimeter tubes,* 10.8 mm. in inside diameter, can be used with the adapter, in the Evelyn macroinstrument.

Construction—The adapter, shown in Fig. 1, is constructed of bakelite. The outside diameter is 22 mm. which permits easy removal from and insertion into the bakelite tube sleeve of the Evelyn. The projection on the bottom of the adapter fits into a slot cut in the inside bottom of the tube sleeve and locks the adapter in place with its aperture opposing the 6 c.c. aperture of the tube sleeve.

The aperture of the adapter is cut slightly larger than that of the tube sleeve, so that the sleeve aperture determines the light path. The inside diameter of the adapter, 12.3 mm., was chosen to accommodate the microtubes. The cut-outs along the side of the adapter permit the operator to guide the tube, which is $4\frac{1}{2}$ inches in length, as it is put into or taken from the adapter. The adapter has an over-all length of 7 and $7/16$ inches including the $3/16$ inch projection.

Performance—The microtubes are calibrated for equality of transmission in the same manner as Evelyn tubes. To obtain a center setting the adapter need be only partially removed until clear of the light beam through the sleeve aperture, this maneuver permits rapid checks of both center settings and readings.

Readings were made with the Evelyn macrocolorimeter with and without the adapter, using the same Evans blue solutions in serial concentrations from 0.0015 mg. per cubic centimeter to 0.0105 mg. per cubic centimeter. One series of results is presented in Table I. The "L values" (photometric density) obtained with the adapter were multiplied by $19.5/10.8$ (the ratio of the diameters of the Evelyn and microtubes) in order to compare the two sets of readings. It may be noted that density values obtained with the adapter, when corrected in this manner for the difference in diameter, agree quite closely with those obtained without the adapter.

TABLE I COMPARISON OF EVELYN MACROCOLORIMETER READINGS WITH AND WITHOUT ADAPTER

CONCENTRATION OF DYE SOLUTION (MG /C G)	READING WITHOUT ADAPTER	L VALUE WITHOUT ADAPTER	READING WITH ADAPTER	L VALUE WITH ADAPTER	L VALUE WITH ADAPTER CORRECTED FOR DIFFERENCE IN DIAMETER OF TUBES
0015	85 ³	0667	91 ³	0374	0675
0030	74 ¹	1278	85	0706	1275
0045	66 ²	1772	79 ³	0982	1772
0060	57 ²	2384	73	1367	2434
0075	51	2924	67 ³	1691	305
0090	45	347	64	1922	347
0105	40	398	59	2291	412

In addition, for any given concentration of Evans blue solution, the adapter gave the same reading with a volume of 1, 2, or 5 cubic centimeters. It appears that use of the adapter successfully increases the volume range of the Evelyn macrocolorimeter from 6 c c down to 1 cubic centimeter.

SUMMARY

A microadapter for the Evelyn macrocolorimeter has been described which permits readings on volumes of solution as low as 1 cubic centimeter. Evidence has been presented to substantiate the validity of results obtained with the adapter.

VENOUS CATHETERIZATION WITH POLYETHYLENE TUBING

SAMUEL L. CRESSON, M.D. * AND WILLIAM W. L. CLENN, M.D. †
PHILADELPHIA, PA.

THE use of polyethylene tubing in the catheterization of veins has been reported by Zimmermann¹ and Meyers.² It is the purpose of this communication to describe and evaluate a method of taking samples of portal vein blood in the ambulatory dog, and to record some of the observations made on the animal reaction to the plastic polyethylene ‡

TECHNIQUE

Under general anesthesia with 1 per cent Nembutal a transverse right subcostal muscle splitting gridiron incision is made. The peritoneum is dissected free by blunt dissection and reflected medially. The portal vein is approached retroperitoneally and is then followed cephalad toward the hepatic border. The peritoneum is frequently opened just as the portal vein is approached. A site is selected just cephalad to the mesenteric radicals in the main trunk of the vein. The loose areolar tissue is dissected away exposing the vein wall. A purse string suture of fine black silk is placed but not tied in the vein wall. Then a No. 16 gauge needle is thrust through the center of the purse string suture, with the end of a small caliber polyethylene tube about 1 1/2 inches long inside the needle bore but not projecting beyond the needle bevel (Fig. 1). Tubing with an internal diameter of 0.023 inch has been found most satisfactory. After piercing the vein wall the cannula is pushed through the needle bore into the lumen of the vein for about 3 centimeters. The needle is then pulled out of the vein and the polyethylene tubing is held stationary by a pair of thumb forceps. As the needle is pulled clear of the plastic tubing the purse string suture is tied. The plastic tubing is then aspirated. If aspiration is adequate several loops of the suture are placed around the tubing, slipped down next to the vein wall and tied again. Sterile saline is injected into the tubing and the end of the tubing sealed by heating the tip of the tubing and then pinching it with forceps while still hot. The same procedure may be used for inferior vena cava catheterization.

We have used as a criterion of an adequate catheterization the aspiration of 5 cc of blood in thirty seconds.

The tubing is brought out retroperitoneally through a separate stab wound and the incision closed. The tubing external to the skin is coiled and is held in place with a piece of gauze saturated with collodion. A firm body encircling adhesive dressing is then applied.

RESULTS

We have performed twenty-four portal vein catheterizations in twenty dogs. The first attempt at aspiration of the vein catheter usually was made seven days after insertion. In four no blood could be aspirated on the first or subsequent trials. In eleven either the animal pulled the tubing out or the tubing fell out or the dog died before aspiration was attempted. A number of the failures could

‡The polyethylene used in the experiments was purchased from the Surprenant Liquefied Gases Company, Boston, Mass. It was furnished us as pure polyethylene without the addition of a plasticizer.

be attributed to preventable errors in technique. The remaining nine catheterizations functioned well for an average of twenty-one days after catheterization. The maximum time adequate blood samples were obtained from the portal vein was thirty-four days. In several animals the portal vein was successfully catheterized two or more times at intervals of several weeks. In only one animal did

Fig. 1—Technique of insertion of fine polyethylene tubing into portal vein lumen.

complete thrombosis of the portal vein result, and this followed three separate catheterizations of the portal vein at two- to three-week intervals, the last tube having been left in the vein for two months.

Although adequate specimens of blood were aspirated for prolonged periods in 37.5 per cent of the experiments, some degree of reaction to the polyethylene tubing was noted in every case where the portal vein was examined.

The first reaction to the polyethylene tubing was the formation of a thrombus surrounding the intraluminal portion of the tubing (Fig. 2). Later, fibrous tissue was laid down over the tube with puckering of the adjacent intimal lining (Fig. 3). These events took place in from two to four weeks after the tubing was inserted into the vein lumen. In one instance the tubing was completely excluded from the vein lumen by fibrous tissue at three weeks. The tip of the tubing remained free in most cases, however, although an area of granulation

was sometimes seen on the intima adjacent to the free tip of the tubing. Attempts to obtain blood samples over periods of several days from veins or small size catheterized with polyethylene tubing were unsuccessful. It is evident from Figs. 2 and 3 that the lumen of a small vein may become occluded promptly.

Fig. 2.—Polyethylene tubing inserted into portal vein four days prior to sacrifice of the dog. Note the thrombus formation surrounding the intraluminal portion of the tubing.

Fig. 3.—Polyethylene tubing inserted into portal vein twenty-two days prior to sacrifice of the dog. Note coiling of excess tubing; arrow points to open end; scarring and puckering of intimal lining around polyethylene tubing. Samples of portal blood were aspirated through tubing for fifteen days.

DISCUSSION

It is apparent from these experiments that catheterization of large veins may be carried out with polyethylene tubing of small caliber and that satisfactory blood samples may be obtained over a period of approximately three weeks.

Fig. 4A—Microphotograph of portal vein $\times 16$. Polyethylene tube inserted into vein twenty days prior to sacrifice of dog. 1, Lumen of vein. 2, Junction of intimal surface of vein wall and tissue overlying polyethylene tube. See Fig. 4B. 3, Fibrous tissue surrounding space where polyethylene tube lay. Tube dislodged or dissolved during preparation of histologic section.

Repeated catheterizations are possible although there is evidence that increasing damage to the vein wall results. The use of polyethylene tubing is an improvement over the London cannula³ for larger vessels but is not satisfactory for vessels of small size.

There has been some controversy over the tissue reaction to polyethylene. Ingraham and co-workers⁴ emphasized the slight tissue reaction to this plastic in the pure form. They believed that the marked fibrous tissue response noted by Poppe and de Olivena⁵ to sheets of polyethylene was due to the presence of a plastizer. For this reason Ingraham and associates⁴ insisted on *pure* polyethylene to which they found only slight reaction when it was buried in cerebral tissue of various experimental animals. Zimmermann¹ did not indicate whether he used polyethylene in the *pure* form, but it is of interest that in two of the four experiments where the veins were examined, thrombosis was found. He was not certain whether this reaction was due to the tubing *per se* or to the infused fluid. There was no infusion of fluids in any of the experiments recorded here except the small amount used to flush the tubing out at the beginning and end of each aspiration. The reaction to pure polyethylene when placed in the lumen of a blood vessel may, however, differ from the reaction in soft tissues.

Fig 4B—Microphotograph of junction of vein wall and fibrous tissue surrounding polyethylene tube. Tub is no longer present ($\times 100$)

due to the formation and subsequent organization of a blood clot surrounding the tubing. It was our impression that the fibrous tissue reaction to the tubing was progressive and that the longer the plastic remained in the lumen of the vessel the more pronounced the reaction became (Figs 4A and 4B). This suggests the possibility of using this material intraluminally for the gradual occlusion of arteries.

SUMMARY

The catheterization of the portal vein for the purpose of obtaining blood samples from the ambulatory dog over prolonged periods can be satisfactorily performed with small caliber polyethylene tubing. The retroperitoneal approach to the portal vein lessens the period of postoperative discomfort and renders the animal available for study at an earlier time. The inferior vena cava is exposed simultaneously by this approach and may also be catheterized.

The presence of pure polyethylene in the lumen of a vein results in a fibrous tissue response that tends to exclude the tubing from the lumen of the vessel.

with narrowing of the lumen of the vein. It is not clear how much of the fibrous tissue reaction is due to the organization of the thrombus that surrounds the tubing. The fact that the fibrous tissue reaction appears to be progressive, however, would seem to indicate that polyethylene per se possesses some irritative action in blood vessels.

The authors wish to acknowledge the helpful advice of Dr. C. Martin Rhode and Dr. William M. Parkins of the Harrison Department of Surgical Research, University of Pennsylvania.

SCREW SYRINGE*

ARNOLD LAZAROW, M.D. PH.D.
CLEVELAND, OHIO

A METHOD for carrying out microcolorimetric capillary tube analysis has been described using pipettes similar in construction to the white blood cell counting pipettes¹. The screw syringe was devised for more precise control of the flow of fluid within the capillary tubes. This screw syringe also can be used to improve the accuracy of diluting blood for cell counts, for controlling the flow of liquids in micropipettes (0.01 to 1 cc) and for controlling the flow of radioactive and other toxic agents within ordinary pipettes thus avoiding the danger of sucking noxious materials into the mouth.

CONSTRUCTION

The syringe consists of the following parts (Figs. 1 and 2): A rubber collar (*A*) contained within the collet (*B*) fixes the pipette firmly in place when the collet is tightened. The body of the control device (*D*) contains the plunger (*F*) as well as the screw control (*E*) for this plunger. Two doughnut shaped 'O' rings (*I* and *J*) seal the plunger within the body (*D*) and within the screw control (*F*). Because 'O' ring (*J*) is compressed more than is 'O' ring (*I*) the plunger (*F*) will turn with the control screw (*E*) upon rotating the latter and this provides the delicate control of the liquid within the pipette. However the plunger can be withdrawn directly from the body without the use of the control screw (*E*) and thus provides a coarse adjustment for the fluid volume. An air vent avoids the displacement of the liquid within the pipette when the latter is removed from the collet. The 'O' ring (*H*) is placed within the body of the syringe and seals the vent hole (*G*) when the collar (*C*) is loose. When the collar (*C*) is tightened the 'O' ring is distorted the hole in the body (*D*) is uncovered and the vent is open. The capacity of the screw syringe is 3 cubic centimeters.

USE OF CONTROL DEVICE FOR BLOOD COUNTING AND BLOOD CHEMISTRY MICROPIPETTES

The collet, containing an appropriate rubber adapter is attached to the syringe body, the pipette is inserted and fixed in place by tightening the collet. The air vent is closed by loosening the collar (*C*), and the apparatus is ready for use. By means of control screw (*E*, Fig. 3) a drop of blood is sucked into the stem of the pipette slightly above the mark, the excess blood is wiped off the tip of the pipette and the blood is adjusted precisely to the mark by simultaneously rotating the control screw and wiping the tip of the pipette on the operator's finger. The tip of the pipette is then placed in diluting fluid (Fig. 4) which is sucked into the bulb of the pipette by withdrawing the plunger (*F*). As soon as the meniscus approaches the upper capillary tube of the pipette, the screw control (*E*) is used to accomplish the final exact adjustment. The pipette is re-

*From the Department of Anatomy, Western Reserve University.

Received for publication Sept. 1948.

The screw syringe is available from the Micrometric Instrument Company, Cleveland, Ohio.

¹The use of the differential 'O' ring pressure was suggested by A. Howard of the Micrometric Instrument Company.

moved from the diluting fluid and the tip carefully wiped with the finger or Kleenex (If Kleenex is used, one must avoid placing it against the tip of the capillary in order to avoid withdrawal of fluid by capillary action)

The index finger of the left hand is placed over the tip of the pipette, and while holding the bulb of the pipette between the thumb and middle finger, the body of the screw syringe is rotated with the right hand, and the pipette is

Fig 1

Fig 1—Screw syringe with micropipette inserted
Fig 2—Construction of screw syringe

Fig 2

removed. The finger seal prevents the displacement of the fluid within the capillary during removal. An alternate method for removing the pipette from the screw syringe utilizes the vent. The pipette and its holder are placed in a near horizontal position, the air vent is opened, the collet is loosened, and the pipette is removed. (If placed in an absolute horizontal position, some pipettes show a slight upward movement of the contained liquid. The upward displacement is due to the fact that adjustment to the upper mark was made in the vertical position against the hydrostatic pressure of the liquid in the pipette, whereas in the horizontal position this pressure no longer exists. However, if the pipette is held at a slight angle, 5 to 20 degrees to the horizontal, the liquid will not rise

above the mark nor will it run out of the pipette when the vent is opened.) Thus all can be accomplished without in any way affecting the position of the meniscus within the micropipette.

 Fig 4—Diluting the blood in the bulb of the pipette using the plunger (F)

USE OF SCREW SYRINGE WITH 1 OR 2 C C PIPETTES FOR RADIOACTIVE OR OTHER TOXIC LIQUIDS

The pipette is inserted into the collet and the vent is closed. By means of the plunger (F) the liquid is sucked up into the pipette above the desired mark. The outside of the pipette may be wiped if desired, the tip of the pipette is then placed against the side of the bottle and the final adjustment to the mark is made with the screw device. The pipette is transferred to the desired container, the vent is opened and the pipette allowed to drain by gravity.

69 THE CRYSTALLIZATION OF SEROTONIN

IRVING H. PAGE, M.D., MAURICE M. RAPPORT, M.D. (BY INVITATION), AND
ARDA ALDEN GREEN, M.D. (BY INVITATION)
CLEVELAND, OHIO

When organs are perfused with blood or serum, progressive vasoconstriction often makes it all but impossible to force blood through them. The substance causing this vasoconstriction has never been identified nor isolated. In view of its probable importance in the vasoconstriction occurring after rupture of thrombosis of vessels such as the coronaries, or after tissue injury in shock, it seemed important to find out something of its chemical nature.

The isolation from beef serum depended on (1) precipitation of beef serum proteins with alcohol, (2) precipitation of salts, phosphatides, and amino acids with acetone, (3) chloroform extraction, (4) extraction of the active principle with butyl alcohol, (5) precipitation of the active principle from butyl alcohol with 5-nitrobarbituric acid, (6) decomposition by addition of acetone to hot aqueous solution, (7) extraction of filtrate residue with warm absolute methanol, (8) recrystallization from water-acetone.

Thin, rhomboid plates (m.p. 212-214°) were obtained which seem homogeneous. Color reactions and ultraviolet absorption indicate the presence of an indole nucleus in the structure. The empirical formula is $C_{11}H_{23}O_3N_2S$. Ionic sulfate analysis suggests that Serotonin is a sulfonic acid salt of an organic base with the formula $C_{11}H_{21}O_3N_2 \cdot H_2SO_4$.

Serotonin is more than twice as active as adrenalin in causing constriction of the vessels of perfused rabbit ears. Isolated strips of rabbit ileum are contracted by it. Injected intravenously into dogs or cats it caused a sharp rise in arterial pressure much like that of adrenalin. The rise was augmented by sympathectomy. It does not appear to produce tachyphylaxis when given repeatedly in small doses.

An enzyme has been prepared from lung which inactivates Serotonin.

70 MANAGEMENT AND CLINICAL COURSE OF LOWER NEPHRON NEPHROSIS

WILLIAM S. HOFFMAN, M.D., AND DANIEL MARSHALL, M.D. (BY INVITATION)
CHICAGO, ILL.

Six patients with lower nephron nephrosis from a variety of causes have been managed by a regimen that included a deliberate, slow induction of edema of nearly normal electrolyte composition for the purpose of diluting the accumulating intoxication products. Other measures were designed to keep the patient in a good state of nutrition. The aim was to keep the patients from dying in uremia before the renal lesion began to subside. Five out of the six patients recovered, the sixth died in uremia and heart failure five days after the onset of diuresis. Four of the recovered patients had complete restoration

to normal renal function. One patient, a child of 2 years, still had moderate renal insufficiency five months after the onset of diuresis. This condition was associated with the development of bilateral encephalitis of the kidneys as seen on x ray.

In these patients, the oliguric phase lasted from five to thirteen days. The serum nonprotein nitrogen rose to levels of 145 to 243 mg per 100 cc and did not begin to subside until several days after diuresis began. Edema occurred early even when fluids were not specially administered. The serum chloride and sodium concentration tended to reach dangerously low levels (in one instance the chloride concentration was 58 meq per liter). This development had to be combated by infusions of 2 per cent salt solution. With careful control of the quantity and composition of the edema fluid symptoms of anemia were minimal, and the patients ate well without vomiting. The leveling of the serum non protein nitrogen concentration during the latter part of the oliguric period was due either to the diluting effect of the edema or to diminished tissue breakdown brought about by the improved nutrition.

71 STUDIES ON PROLONGED SUPPURATIVE INFECTION IN MAN

GEORGE W. JAMES III, M.D., LILLIAN A. RIBLET, M.D., JOSEPH C.
ROBINSON, M.D., ROBERT E. JOHNSON, M.D., AND ROBERT M.
MARK, M.D., CHICAGO, ILL.

(INTRODUCED BY ROBERT W. KEETON, M.D.)

Despite advances in surgical techniques and the vigorous use of blood and plasma transfusions, sulfonamide derivatives and antibiotic substances, suppuration persists in a number of patients with infected traumatic injuries. Therefore, during the past year clinical bacteriologic and laboratory studies were made on ninety one young men suffering with chronic suppurating lesions of the bones, kidneys and other soft tissues. A group of twenty seven patients and ten bedridden control subjects were studied more intensively than the remaining sixty four patients.

Although the average period of hospitalization was twenty three months at the beginning of observation fair nutritional status was maintained. There was an average weight loss of 7.9 kilograms but no clinical evidence of vitamin or protein deficiencies.

Sixty three per cent of the patients were infected with *Staphylococcus aureus*. Pathogenic spore bearing organisms *Placmobacterium aerogenes*, *Aerobacter aerogenes*, and gamma (nonhemolytic) streptococci were frequently isolated. Multiple infections and concurrent self-contamination were common findings, and a correlation was found between hemoglobin levels and numbers of different species of organisms in the wound. The more different genera of organisms the lower the hemoglobin levels.

Hematologic data were essentially normal. Anemia was a rare finding. Blood and plasma volumes were increased 10 to 20 per cent when expressed as a function of body weight. Total circulating hemoglobin was significantly reduced in those patients with severe infections. A marked predominance of small spherocytic reticulocytes was observed, but no other aberrant cells were seen.

Depression in serum iron and elevation of serum copper levels were more marked in patients with severe infection. Serial studies during spontaneous remissions indicate an initial shift of serum copper levels toward normal. This is followed at a later date by elevation of serum iron levels. Preliminary observations following daily oral administration of 60 mg cobalt chloride reveal a reticulocytosis during the third to fifth week of therapy and increases in red blood cell count, hemoglobin levels, hematocrit, and total circulating hemoglobin.

complex possesses antibiotic activity. Normal human subjects were given crystalline penicillin G following which a 500 ml blood sample was fractionated into its various protein fractions. The penicillin was almost quantitatively recoverable in fraction VI, which in retentivity represents that portion remaining after all other fractions have been precipitated. The plasma control assays for penicillin and the fraction VI assays were identical in each instance. Additional studies were carried out by dialysis of whole plasma and some of the various fractions under temperature conditions that would not be deleterious to penicillin. There was no evidence of inactivation or antagonism of the penicillin by any of the protein fractions nor evidence of any combination with the protein fractions in the dialysis experiments. Similar studies under way with bacitracin seem analogous.

74 THE ANESTHETIC AND ANTIHISTAMINIC ACTION OF A SERIES OF ANTIHISTAMINIC DRUGS IN HUMAN SKIN

JOHN U KEATING, MD (BY INVITATION) AND CHARLES F CODE MD
ROCHESTER MINN

The anesthetic potency and the antihistaminic action of equimolar concentrations of Benadryl, Pyribenzamine, Neocatergan 3015 RP and 3277 RP were determined in the skin of normal human subjects. In descending order of anesthetic potency, the drugs ranked 3277 RP, 3015 RP, Pyribenzamine, Neocatergan, and Benadryl. In descending order of the ability of the drugs to inhibit histamine flares they were Pyribenzamine, Neocatergan, Benadryl, 3015 RP, and 3277 RP. The findings that those compounds which have the greatest local anesthetic potency are not those with the greatest antiflare effects supports the view that the flare inhibiting property of these synthetic antihistaminic drugs is not directly dependent on their local anesthetic activity and there is thus a separation between antihistaminic and anesthetic actions.

75 FAILURE OF ANTIHISTAMINIC DRUGS TO REDUCE REACTIVE HYPEREMIA IN MAN

MILTON F ANDOWNF MD AND WALTER S THOMPSON MD (BY INVITATION)
CHICAGO ILL

In the classic studies of Lewis and Grant on reactive hyperemia evidence was presented suggesting that this vasodilatation was due to the accumulation of a chemical in the region of circulatory arrest. Barsoum and Smirk reported that a substance with the biologic properties of histamine could be detected in the venous blood during reactive hyperemia in concentrations up to 0.6 gamma per cubic centimeter. This evidence together with the implication of Lewis studies has led to a tacit acceptance of the concept that reactive hyperemia is primarily due to the accumulation of histamine like substance. The following observations, in which reactive hyperemia could not be reduced by antihistaminic drugs, seriously challenge the validity of this concept.

Reactive hyperemia was produced by the application and release of an inflatable occluding cuff placed about the thigh in seven subjects. These included normal subjects and one hypertensive patient before and after sympathectomy. Measurements of volume change and blood flow in the foot were made by means of a venous occlusion plethysmograph. Occlusions were maintained to produce manifest hyperemia (five to ten minutes) and threshold or minimal responses as well (one half to three minutes). The initial inflow after release

of occlusion was considered to reflect the dilatation produced. After a period of control observations of resting flow and reactive hyperemia, Benadryl (beta dimethylaminoethyl benzhydryl ether hydrochloride), 10 to 30 mg intravenously, or Pyribenzamine (beta-dimethyl-aminoethyl-2-pyridyl-benzyl ammonium chloride), 50 mg orally, was administered. Observations were repeated at intervals for a period of more than one hour. No diminution was detected in the circulatory response to arterial occlusion. The summarized averaged blood flows in cubic centimeters per minute per 100 cc limb volume, with the number of determinations in parentheses, are as follows:

	RESTING	REACTIVE HYPEREMIA
Before drug	2.70 (134)	8.33 (39)
After drug	2.62 (99)	8.78 (36)

There was no essential difference between different subjects or after varying durations of occlusions.

In several instances the intradermal injection of 0.1 to 1.0 gamma of histamine base demonstrated the effectiveness of the antihistaminic drug.

76 CLINICAL OBSERVATIONS ON HISTAMINE ADMINISTRATION DURING PREGNANCY

THOMAS W. McELIN, M.D. (BY INVITATION), AND BAYARD T. HORTON, M.D.
ROCHESTER, MINN.

The recent obstetric, physiologic, and pharmacologic literature continues to discuss the oxytocic effect of histamine in women and in animals. As recently as 1946, editorial comment in the *Obstetrical and Gynecological Survey* remarked that histamine exerts a powerful stimulating effect directly on the myometrium. An impressive array of experimental literature may be found to document this opinion. Two of the earlier studies conducted were those of Hotbauer and of Bourne and Burn. The former author pointed out that uterine spasm is one of the observable responses in acute histamine poisoning in pregnant guinea pigs. Bourne and Burn in 1927, utilizing intrauterine bags with manometer attachments in parturient women, demonstrated that histamine injected subcutaneously in a dose of 2.0 mg (reckoned in terms of base present) produced powerful but short-lived uterine contractions.

In the course of a prolonged program of clinical investigation and treatment of the so-called vascular diseases, allergic diseases, and certain atypical pain patterns not amenable to more usual forms of treatment, we have had occasion to administer or to prescribe the administration of histamine by the intravenous or subcutaneous route to fifteen pregnant women. In view of the apparent pharmacologic inconsistency of such therapy and because of the complete absence of any undesirable sequelae of such treatment, we wish to record our observations.

Our fifteen patients (twelve of whom had received a diagnosis of multiple sclerosis) were treated in a five-year period ending April, 1948. During this time approximately 70,000 intravenous injections of histamine were given and some 4,600 patients were seen in our laboratory. The series of pregnant patients included both primigravidae and multigravidae. Six patients received subcutaneous injections of histamine daily throughout the entire period of gestation. Intravenous injections of this drug were given in every month of pregnancy and in two instances the injections were given three times weekly throughout the entire third trimester to within three days of delivery. In thirteen of the fourteen patients who have thus far been delivered, there has been no

tendency to premature labor. Twelve of these fourteen have had their labor after the expected date of confinement.

The maximal amount of histamine given was administered to a primigravida, 23 years of age, who had multiple sclerosis. This patient received forty-five intravenous injections each of which contained 2.75 mg. of histamine diphosphate (10 mg. of histamine base) during the third, fourth, and fifth months of her pregnancy.

Only one event which might in any way be construed as representing an untoward effect on the pregnant uterus occurred in the entire series. A primigravida, 29 years of age, sustained one episode of slight vaginal bleeding twelve hours after a subcutaneous injection of 0.137 mg. of histamine diphosphate (0.05 mg. of histamine base). The month of the pregnancy in which this bleeding occurred is not known. This is one of the smallest amounts of histamine given to any patient in the group so that the significance of this observation is questionable.

We wish to suggest on the basis of our experience that there is at least an apparent lack of a clinical oxytocic effect of histamine diphosphate when it is administered to pregnant women by the subcutaneous or intravenous route or by both routes in the therapeutic dosages mentioned. We offer no preferred explanation as to why the oxytocic effect described by so many authors and attested by abundant laboratory study did not occur. A few of the possible explanations which immediately present themselves are: (1) that the elevated histaminase level known to occur in pregnant women might be responsible for the inactivation of the injected histamine; (2) that the dosage of histamine used was not adequate to provoke a clinically observable oxytocic response; (3) that the altered neurogenic response in the twelve patients in this series who had multiple sclerosis may in some way in these patients have altered the predicted effect.

77 RETROBULBAR NEURITIS, TREATMENT WITH HISTAMINE

BAYARD T. HORTON, M.D., and HENRY P. WAGENER, M.D. (BY INVITATION)
ROCHESTER, MINN.

WITH THE TECHNICAL ASSISTANCE OF EVELYN F. HELGERSON, M.A.

The typical syndrome of retrobulbar neuritis consists of lowered visual acuity, some form of scotoma in the visual field, and usually a normal appearing nerve head. In both the acute and chronic forms of this syndrome edema and interference of the blood supply to the optic nerve are evident. The axillary cylinders will withstand ischemia for considerable time before final degeneration begins. A vasodilating agent which will increase materially the blood supply to the optic nerve is the most satisfactory means of restoring its function. Spontaneous recovery may and frequently does occur, but in our experience unless it begins within three weeks after the onset of symptoms, it will not be complete.

Histamine is the most powerful vasodilating agent available for increasing the blood supply to the central nervous system; hence the rationale for its use in the treatment of retrobulbar neuritis. Compared with other forms of treatment it is more universally applicable, is less discommoding to the patient, does not necessitate hospitalization, and seems to result in more rapid and complete recovery of vision.

In this study we have employed a 1:250,000 dilution of histamine administered intravenously by the drip method at rates varying from 24 to 48 drops

per minute. The rate employed depended on the patient's tolerance. Treatment for one and one-half hours has been carried out daily or every other day for from one week to three and one-half years. No untoward reactions have been observed. One patient received 410 treatments. In the light of our recent experiences it is obvious that some of our earlier patients had inadequate treatment.

During the past six years we have administered histamine to sixty-one patients who had retinobulbar neuritis. Of these sixty-one patients, thirty-four were women and twenty-seven were men. The ages ranged from 9 to 49 years, with an average age of 30.5 years.

Eighteen patients previously had been given typhoid vaccine intravenously. None of the eighteen regained normal vision, seven obtained 25 to 75 per cent improvement in vision, ten noted no change, and one experienced greater loss of vision after treatment with typhoid vaccine. When these same eighteen patients were treated with histamine administered intravenously, five regained normal vision, five obtained 25 to 75 per cent improvement, and eight noted no change.

Forty-three of the sixty-one patients had not had previous treatment with typhoid vaccine but did receive histamine intravenously. Of these forty-three patients, nineteen regained normal vision, three obtained 75 per cent recovery, six, 50 per cent recovery, five less than 25 per cent recovery, and the remaining ten noted no change.

Twenty-two of the sixty-one patients had had visual loss for more than one year, five of these regained normal vision. Five of the sixty-one patients had had visual loss for six months to one year and none of these regained normal vision. Eight of the sixty-one had had visual loss for three to six months and six of these regained normal vision. Twenty-one of the sixty-one patients had had visual loss for one month or less, twelve of these regained normal vision. Five of the sixty-one patients were unable to furnish definite data as to the onset of their visual loss and of this group one obtained normal vision.

In summary, it is interesting to note that twenty-four of the sixty-one patients regained normal vision and that the vision of ten improved 50 to 75 per cent. Although eighteen of the sixty-one patients had had previous treatment with typhoid vaccine, none of the group had normal vision following this type of treatment. However, when histamine was administered intravenously to this same group of patients, five regained normal vision.

78 THE PREPARATION AND PROPERTIES OF MAMMALIAN STRIATED MYOFIBRILS

ARMIN F. SCHICK, M.D. (BY INVITATION), AND GEORGE M. HASS, M.D.
CHICAGO, ILL.

A physicochemical method for isolation and purification of myofibrils from mammalian skeletal and cardiac muscle has been devised. Blocks of young fresh muscle were frozen and cut into thin sections with a freezing microtome. The sections were transferred directly to a proteolytic enzyme buffer solution (0°C , pH, 7, ionic strength, 0.25). After digestion at 0°C for thirty to forty-five minutes, the myofibrils were separated by mild mechanical agitation. Following this, the segregated myofibrils were separated from other cellular and interstitial components of muscle by controlled centrifugation.

The isolated myofibrils which were obtained in large quantities by this method had characteristic physical properties. They varied in length and

breadth but retained the essential microscopic structural detail, plasticity and birefringence, characteristic of myofibrils in their normal intracellular location, prior to application of the procedure for isolation. They were soluble in a slightly alkaline reagent (0.5 normal potassium chloride plus 0.03 normal sodium bicarbonate) giving viscous solutions which displayed a strong birefringence of flow. In buffer solutions with an ionic strength of 0.15, the myofibrils dissolved on the acid side of pH 4.0 and on the alkaline side of pH 10.0. In phosphate buffer solutions with an ionic strength of 0.5 the myofibrils dissolved when solutions were on the alkaline side of pH 6.3. In phosphate buffer solutions with the ionic strength increased from 0.15 to 0.5 by addition of potassium chloride, the myofibrils were soluble when solutions were on the alkaline side of pH 6.0.

The isolated myofibrils, although probably modified in some respects by tryptic action and mechanical agitation during isolation at 0° C., exhibited the property of contractility when placed in dilute neutral solutions of adenosine triphosphate. Under these conditions myofibrils isolated from skeletal muscle of man and rabbit contracted rapidly so that long fibrillar structures with sharply defined microscopic characteristics were converted irreversibly into spherical masses with no recognizable structural detail.

79 CASTOR BEAN SENSITIVITY

W. P. GARVER, M.D., CLEVELAND, OHIO

Five men working in a mill where castor bean is processed complained of allergic symptoms associated with this occupation.

The five were skin tested with seven extracts of castor bean products. All of them had a positive reaction to one or more of the extracts. Three of the five were then tested by the Prausnitz-Kustner passive transfer technique. The reagins identified by this method were identical with the positive tests obtained by direct skin testing. An extract of castor pomace gave a positive test in all five patients. All of the patients associated contact with this substance with their clinical symptoms.

Thirteen control subjects were skin tested with the same extracts. Eight failed to react to any of the castor extracts. Three gave slight irritative non-specific reactions. Two control subjects reacted in some degree to most of the extracts. The latter two were foundrymen suffering from asthma. The relationship of these positive tests to their asthma has not been determined.

80 BERYLLIOSIS: OBSERVATIONS AND REPORT OF CLINICAL STUDY OF SEVENTY CASES OF CHRONIC DISEASE

WILLARD MACHLE, M.D., NEW YORK, N. Y.

Berylliosis may be defined as a general disease characterized chiefly by pulmonary insufficiency and having the major pathologic changes in the lung. It results from the inhalation of finely divided beryllium compounds.

The epidemiology and etiology of the disease are discussed, and a summary of the clinical study of seventy cases of chronic disease is presented. Report is made upon chemical findings in the tissues of persons with fatal cases and the pathologic anatomy of the disease is discussed briefly. Data on concentrations of beryllium in the air of plants are reviewed. X-ray films from representative cases will be presented.

81 CORRELATION OF LACTOBACILLUS COUNTS WITH EXTENT OF DENTAL CARIES IN AN INSTITUTIONAL POPULATION

JULIAN D BOYD, M D, V D CHEYNE, D D S (BY INVITATION), AND
K E WESSELS, D D S (BY INVITATION), IOWA CITY, IOWA

Lactobacillus counts from the saliva of more than 200 institutionalized children have been made in a State Laboratory by personnel especially trained to provide such service to the dentists of the state. Duplicate analyses of samples collected within twenty-four to forty-eight hours were made for most of the subjects. All samples were collected before breakfast and before cleaning of the teeth after the subjects chewed paraffin.

The individual lactobacillus counts were correlated with the extent of tooth decay (number of DMF surfaces), the rate of progression of tooth decay during the previous nine to twenty-one months, and the status of mouth hygiene. No correlation was evident except with the habitual and the current state of oral hygiene. The data offer nothing to support the premise that lactobacillus counts provide a diagnostic or prognostic index of the activity of dental caries. Any apparent relationship evidently relates to the hygiene of the oral cavity and the areas for lodgment of pabulum for bacterial growth rather than to the process of caries in itself.

82 ACUTE TORTICOLLIS DUE TO FOOD ALLERGY

THERON G RANDOLPH, M D, CHICAGO, ILL

Repeated attacks of acute torticollis have been observed to follow the ingestion of allergenic foods in each of three specifically sensitized patients.

Although the symptoms of tightness, pulling, aching, and tenderness of the posterior cervical muscles, with and without associated headaches, have been observed as manifestations of chronic food allergy and such symptoms have been induced following the experimental ingestion of allergenic foods, instances of acute torticollis have not been described on this basis. As a rule, recurrences of cervical myalgia on an allergic basis do not go on to the development of acute torticollis.

The most favorable circumstances for the development of an allergic writhing neck include the presence of a high degree of specific sensitivity to a commonly ingested food which previously had been avoided for at least three or four days prior to an evening feeding of this food. This, in turn, is usually associated with an allergic reaction of such severity as to cause the patient to retire shortly after the evening meal. Motion on turning in bed during sleep, upon arising from bed the following morning, or within the first half hour after arising may be associated with the sudden onset of an excruciatingly severe pain sharply localized to a small exquisitely tender area in the trapezius or sternocleidomastoid muscles. Contraction of the involved muscles with immobilization of the head in a position favoring the shortening of the affected muscle or muscle groups immediately results as a protective measure because of the extreme pain on motion of the head. A relatively fixed position of the head and shoulders is maintained for one or two days following which the attack gradually subsides coincident with a decrease in the hypertonicity, aching, pain, and tenderness of the affected muscles.

83 THE EFFECT OF VARYING THE DOSE OF IODINE ON THE BEHAVIOR OF RADIOIODINE TRACERS IN PATIENTS WITH EXOPHTHALMIC GOITER

D S CHILDS, JR, M D (BY INVITATION) I R KRYTING JR M D M M D
WILLIAMS, PH D (BY INVITATION), AND M H POWER, PH D
ROCHESTER, MINN

Five patients who had exophthalmic goiter received repeated tracer doses of I^{131} by mouth, with varying quantities of stable sodium iodide as carrier. The behavior of each dose was followed by means of serial measurements of the intensity of radiation over the thyroid gland and abdomen, and of the concentration of I^{131} in blood serum and urine.

Where small quantities of iodine (1 to 100 μ g) were used a large proportion of the dose was accumulated and retained in the thyroid gland. The quantity of I^{131} in the thyroid gland increased exponentially for six to twenty-four hours and thereafter decreased very slowly.

When large quantities of iodide (10 mg) were employed little or none of the dose remained in the thyroid gland and a large proportion (80 per cent) appeared in the urine. Observations over the thyroid gland revealed a prompt but temporary accumulation in the thyroid gland which reached a peak representing 15 to 35 per cent of the dose within three hours. Subsequently, the radioiodine content of the thyroid gland decreased rapidly until at twenty-four hours only a small fraction remained. This decrease of I^{131} in the thyroid gland occurred at a rate comparable to but somewhat slower than the rate of disappearance of radioiodine from the blood.

When an intermediate quantity of iodide (10 mg) was used the curves describing the changes in concentration of I^{131} in the thyroid gland appeared to be composites of those obtained in the high and low carrier groups. The rate of disappearance of radioiodine from the blood and the quantities eventually accumulated in the thyroid gland or excreted in the urine likewise were intermediate between the other groups.

It is suggested that the iodine accumulating function of the hyperactive thyroid gland observed after the use of small doses of labeled iodide is largely or entirely related to the synthesis and storage in the thyroid gland of organic compounds containing iodine.

The function of the hyperactive thyroid gland which is observed when large doses of iodide are administered appears to be similar to that described by Astwood in the normal human thyroid gland blocked with antithyroid drugs and appears to represent the storage within the thyroid gland of iodide as such.

The function of the kidney with respect to the excretion of iodide did not appear to be materially altered over the range of doses herein employed.

84 EVALUATION OF THE USE OF ANTERIOR PITUITARY EXTRACT IN THE TREATMENT OF PITUITARY DWARFISM

JOSEPH C EDWARDS M D CECIL M CHARLES M D (BY INVITATION) AND
CYRIL M MACBRIDE, M D ST LOUIS, MO

This study was based on the treatment of eleven dwarfs with pituitary growth extract. Eight patients exhibited all of the characteristics of pituitary dwarfs. Case 4 had had satisfactory treatment for congenital syphilis. A twelfth dwarfed patient with normal epiphyses and genital development reached normal size in two years with treatment by desiccated thyroid 0.06 Gm daily.

alone Case 6 had had Pott's disease of the tenth dorsal vertebra Cases 3, 6, and 7, although having the appearance of pituitary dwarfs with genital and general physical underdevelopment, had no delay in epiphyseal development for their ages

Method of Study—After preliminary periods of observation with accurate anthropometric measurements, each of the eleven patients was given Phyone pituitary extract (Wilson), which contains both growth and thyrotropic factors An initial dose of 0.25 c.c., then doses of 0.5 and 1.0 c.c. on alternate days were given intramuscularly A 2.0 c.c. dose thrice weekly was continued for two to six months with control intervals without treatment

Basal metabolic rates were normal in all but three patients No patient had myxedema Cases 1, 4, and 8 received daily doses of 0.03 to 0.12 Gm of desiccated thyroid daily in addition to Phyone treatment because of slightly subnormal basal metabolic rates Case 11 received thyroid a short time to note any added effect on growth, no significant change was noted The other eight patients receiving Phyone were not treated with any thyroid, androgen, or estrogen during their observation on Phyone treatment

Blood counts, hemoglobin, urine analyses, and blood Kahn tests were normal Roentgenograms of the skull were normal in nine patients, and two had bridging of the clinoids with small sella turcicae

Results—Case 3 was the only one of the eleven whose height and weight at the end of treatment exceeded the minimum average height and weight for his age The normal growth curves for boys and girls are shown in the same scale as the growth curves of this group for comparison

Our patients failed to show an increase in stature or weight so definite that it could be attributed to the use of the growth extract Phyone alone

Conclusion—Further studies with more potent pituitary growth hormones are needed before one can unreservedly recommend the use of commercial growth hormones for prolonged treatment of pituitary dwarfism

85 EFFECT OF INSULIN ON TUBULAR REABSORPTION OF GLUCOSE IN DIABETIC PATIENTS

MELVIN M. CHERTACK, M.D. (BY INVITATION), LUKE J. GRIMELLI, M.D. (BY INVITATION), HELEN L. RHETTA, M.D. (BY INVITATION), AND ROBERT W. KETTON, M.D., CHICAGO, ILL.

In 1941 Shannon and associates reported a 10 per cent reduction of the renal tubular reabsorption of glucose (TM_G) in four out of six dogs following an injection of 50 units of insulin Creatinine was used to measure glomerular filtration The ratios of TM_G subsequent to insulin divided by their values prior to insulin were 0.88, 0.89, 0.87, 1.06, 0.77, and 0.96

In our studies five adult male patients, ages 18 to 33, known to be diabetic for one to eight years, were used They showed no clinical or laboratory evidence of hypertension, renal disease, or other complications They were readily desugared on insulin and were classified as insulin sensitive Insulin dosages varied from 10 to 35 units of crystalline and from 20 to 50 units of protamine

The patients were stabilized on diet and insulin On the morning of the insulin experiment the daily doses of protamine and crystalline insulins were given, the glycemic level was raised, and the TM_G values were determined through three periods Several days later after the protamine insulin had been withheld for not less than forty-eight hours and crystalline insulin for twenty-four hours, the experiment was repeated The ratios of TM_G after the insulin

divided by their values without insulin were 0.98 0.92 0.83 0.83 and 0.77 respectively for the five subjects. It has been generally recognized that variation from period to period in TM_G determinations may be large.

The plan used by other workers of averaging the values for three successive periods to secure the TM_G of the patient was followed. Although these values were depressed consistently after the administration of insulin the degree of depression was not regarded as significant in view of the limitations of the method.

It should be realized that all of the patients had an endogenous supply of insulin in addition to the injected supply. One may therefore conclude only that a deficiency in insulin does not interfere significantly with tubular reabsorption of glucose.

86 EFFECT OF HYPERGLYCEMIA ON THE CLEARANCES OF INULIN AND PARA AMINOHIPPURIC ACID

L. J. GRIMELLI, M.D., M. M. CHERTICK, M.D., H. L. RHETTA, M.D.,
A. B. KENDRICK, PH.D. AND R. A. LORRIS, M.D. CHICAGO, ILL.

(INTRODUCED BY ROBERT W. KEFTON, M.D.)

Early in our studies of renal function in the presence of hyperglycemia certain discrepancies in the determination of PAH clearance were noted. Klopp, Young and Taylor reported that hyperglycemia may decrease the PAH clearance from 30 to 80 per cent but not effect the clearance of mannitol. It seemed wise to study this problem further.

In the present studies to be reported insulin was maintained at levels of 20 to 75 mg per cent, the para aminohippuric acid (PAH) at 0.9 to 3.5 mg per cent, and the glucose at normal fasting to hyperglycemic levels.

Thirteen patients of whom seven were women and six were men were studied. The previous clinical data had shown normal kidney function. The experiments were done in the following manner: (1) at normal glycemia and low levels of PAH, (2) at hyperglycemia and low levels of PAH, and (3) at hyperglycemia and high levels of PAH. The inulin clearance rose slightly but progressively under the experimental conditions enumerated. This rise was not significant since it fell within the limits of the standard deviation of the method. All values were corrected to a surface area of 1.73 square meters. At fasting blood sugar levels the PAH in women averaged 593.8 ± 126.3 cc per minute, and at hyperglycemia 407.1 ± 146.1 cc per minute. The average depression due to hyperglycemia was 31.4 per cent.

In the men the PAH_c at fasting glucose levels averaged 654.9 ± 105.3 cc per minute, and at hyperglycemia 312.5 ± 119.5 cc per minute, with an average depression of 52.5 per cent. The depression of PAH_c was reproduced on separate days in one patient. At fasting glucose levels the TM_{PAH} was 76.9 mg per minute and at hyperglycemic levels the TM_{PAH} was 54.0 mg per minute. The average depression due to hyperglycemia was 29.8 per cent.

Hyperglycemia depresses the PAH_c and the TM_{PAH} values. Sufficient experiments have not been conducted to establish correction factors. The competitive antagonism between glucose and para aminohippuric acid as it affects tubular function is now under investigation.

87 CHOLESTEROL TOLERANCE TESTS IN NORMAL, DIABETIC, AND HYPERTENSIVE PATIENTS

E D FUTCH, M D, AND RAYMOND GREGORY, M D, GALVESTON, TEXAS

The possibility that intimal atherosclerosis is due in some instances to a basic metabolic fault in the capacity to utilize cholesterol caused us to devise a cholesterol tolerance test which will be briefly described

This test was performed on fourteen normal subjects, four patients with essential hypertension, eleven patients with diabetes mellitus, 23 to 79 years of age, one patient with hypercholesterolemia and xanthomatosis of the skin, one patient with nephrotic stage of chronic glomerulonephritis and hypercholesterolemia, one male patient, 25 years of age, with acute myocardial infarction and normal serum cholesterol

Repeated analyses established that the method entailed a maximal error of 5 per cent In the group of fourteen normal subjects, the total free cholesterol increased from 4 to 38 per cent, cholesterol ester increased 0.8 to 24 per cent Maximal increases were distributed from the second to the eighth hour In two subjects the free and ester forms fell 5 to 18 per cent

The results in the eleven diabetic patients were the same as in the normal subjects in all essential respects The results in four patients with essential hypertension likewise were within the range shown by normal subjects In the patient with skin xanthomas and in the patient with nephrosis, both of whom had hypercholesterolemia, the blood levels of both free and ester forms of cholesterol fell 3 to 19 per cent during the tolerance test

The only abnormal results were found in the 25-year-old man with acute myocardial infarction In his case the free cholesterol rose 43 per cent and the cholesterol esters rose 29 per cent The maximal rise in free cholesterol in the normal group was 38 per cent in one instance, with an average maximal rise of 17 per cent The maximal rise in cholesterol ester in the normal group was 24 per cent, with the average maximal rise of 9 per cent

These data do not demonstrate any difference between normal, hypertensive, and diabetic subjects in their response to a cholesterol tolerance test This indicates that the tendency of the diabetic and hypertensive patient to develop intimal atherosclerosis is not due to a prolonged or excessive postprandial hypercholesterolemia

88 THE MEDICAL AND METABOLIC FACTORS IN THE SURGICAL MANAGEMENT OF HYPERTHYROIDISM

I DARIN PUPPEL, M D, COLUMBUS, OHIO

The goitrogens are by no means solely responsible for the decreased morbidity and mortality following the modern thyroidectomy There are a multitude of factors which must still be considered in the proper surgical treatment of the patient with hyperthyroidism in addition to the use of the goitrogens

A summary of consecutive thyroidectomies on 400 goitrous patients from 1937 to 1942, and prior to use of our present regimen, revealed 185 to be for nontoxic goiter and there resulted no hospital deaths Two hundred fifteen were for hyperthyroidism and these accounted for an unusually high degree of morbidity and mortality so that the total mortality averaged 2.25 per cent During this same period four pole ligations were done and ten thyroidectomies were staged, followed by a high mortality The causes of death included thyroid crisis, respiratory failure, massive atelectasis, bronchopneumonia, acute cardiac failure or shock, and liver death These represent to a great extent avoidable

causes of death in the light of our present methods of treatment. Consequently, a summary of consecutive thyroidectomies on 400 goitrous patients treated by our present regimen from 1943 to 1948 revealed 157 to be for nontoxic goiter, and there occurred no deaths. Two hundred forty three were for hyperthyroidism which is a greater number than in the former group. Furthermore, the severity of the hyperthyroidism in this group was usually greater and the complications were more frequent. Yet there resulted no deaths. No ligations were done and only five thyroidectomies were staged but with no deaths.

In our experience, there are two groups of medical and metabolic factors which have led to this lowered morbidity and mortality rate of the modern operation. The first includes seven general factors and major developments which have made all modern surgery less hazardous. The second group embraces at least nine specific factors related to hyperthyroidism which have counteracted the deleterious hypermetabolic effects of the disease.

The clinical use of the goitrogens and internal radiotherapy is still in many ways in the experimental stage. When a physician contemplates the use of one of these substances he should seriously consider the general and specific factors in the treatment of toxic goiter in addition to the new substance in order to serve the best interests of the patient.

89 THE BETA GLUCURONIDASE ACTIVITY OF HUMAN ENDOMETRIUM

LESTER D. ODELL, M.D. AND WILLIAM H. FISHMAN, Ph.D. (By Invitation)
CHICAGO, ILL.

Endometrial biopsies (suction curette) were obtained from thirty-two women at various days of the normal menstrual cycle. The specimens were weighed, homogenized, and assayed for β glucuronidase activity using the method of Fishman, Spranger and Brunetti (J. Biol. Chem. 173: 449-456, 1948).

The β glucuronidase activity increased during the first two thirds of the menstrual cycle, followed by a decline particularly in the last three days of the cycle. The presence or absence of progesterational endometrium seemed to bear little reference to these changes. These results would indicate that the β glucuronidase activity of endometrium parallels the estrogen secretion reported for the menstrual cycle.

Multiple specimens of endometrium were obtained from the same patients and assayed independently. While there was some variation in results, it was insufficient to disturb the general pattern described here.

β glucuronidase is believed to play a fundamental role in the physiologic action of the estrogenic hormones. The cyclic change in activity observed in the endometrium parallels the histologic effect of estrogen stimulation. Therefore it is possible that endometrium normally participates in the metabolic conjugation of estrogenic hormones.

90 DIFFUSE PANCREATIC CALCIFICATION WITH DIABETES MELLITUS

BRUNO J. PETERS, M.D., M. C. I. LINDERT, M.D., MARTIN J. KLAPMAN, M.D.
AND DANIEL J. MENDELSON, M.D. MILWAUKEE, WIS.
(Introduced by MAURICE HARDGROVE, M.D.)

The present study is one of the association of pancreatic calcification with diabetes mellitus. In addition to four cases observed clinically, there are three cases of pancreatic calcification from which autopsy findings are presented. It

has been suggested that disseminated pancreatic calcification be recognized as a distinct clinical entity. We feel that it is impossible to differentiate clinically disseminated calcification from multiple calculi in the pancreas. The etiology of the change is unknown. Alcoholism was the one most frequent, suspicious, predisposing cause in our cases. The symptoms simulated those of gall bladder colic, perforated ulcer, and appendicitis. It is suggested that a scout film be taken in acute abdominal conditions generally and in a diabetic patient particularly. In this way more cases will be recognized and erroneous surgery will be prevented. Also, with the advent of recent advances in pancreatic surgery, it is conceivable that partial or total pancreatectomy may be helpful in relieving the intractable pain present in some of the patients.

91 PSEUDOHYPOPARATHYROIDISM

CASE REPORT

M. G. PETERMAN, M.D., AND J. L. GARVEY, M.D. (BY INVITATION)
MILWAUKEE, WIS.

A 12-year-old girl was examined because of logorrhea, mental retardation, and convulsions. The patient's condition had been diagnosed as epilepsy and hypothyroidism. The mother was ill during pregnancy and almost miscarried in the fourth month. Delivery and infancy were normal. The infant was always hungry, never lost infantile fatness, always had a hoarse voice, and often a crowing inspiration. At 2 years she complained of numbness and tingling in the extremities.

The patient weighed 101 pounds and her height was 58½ inches. She had a round, pudgy face with a slightly yellow pallor of the skin and a generalized myxedematous appearance. Chvostek's sign was strongly positive as were the ulnar and peroneal reflexes. The Trousseau test was negative. The voice was hoarse and coarse. There were several areas of calcification in the skin. The mouth was kept in a "carp" position.

The girl had repeated episodes of sudden squealing or shouting with pupils dilated and without loss of equilibrium. The mouth was held open, the extremities were tense. There were five to fifteen seizures in each twenty-four hours.

The serum calcium was 6.6, phosphorus, 11 milligrams. The urinary phosphorus excretion was 0.7 Gm. in twenty-four hours. The Sulkowitch calcium test of the urine was negative throughout.

Lateral x-ray of the skull showed scattered areas of calcification in the basal nuclei and generalized osteoporosis. This osteoporosis was also found in all of the long bones.

The electrocardiogram showed a marked increase in the Q-T interval.

$$K = \frac{Q-T}{RR} = 51$$

The electroencephalogram showed spiking, slow 6 per second waves, a big build-up on hyperventilation with 3 per second waves not typical of the dysrhythmia of epilepsy.

The Binet-Simon test gave an I.Q. of 79, the Rorschach test "there is much in the structure of the record and in the child's behavior during the test to indicate an organic brain disturbance of an epileptic or convulsive type."

An intravenous pyelogram showed normal kidneys and ureters. The Mosenthal test was negative.

There has been a good response to treatment with high calcium, low phosphorus acid ash diet. Treatment with parathyroid extract was ineffective. Treatment with acid ash high calcium, low phosphorus diet plus Hytakerol brought the blood chemistry to normal. However, the seizures have persisted.

No case of hypoparathyroidism or of the pseudo type has been reported with osteoporosis of the bones.

92 PREMATURE CALCIFICATION OF THE COSTAL CARTILAGES ITS FREQUENT ASSOCIATION WITH PSYCHONEUROSES AND POSSIBLE ENDOCRINE IMBALANCE

JOHN L. HORNER, M.D., St. Louis, Mo.

(INTRODUCED BY S. B. GRANT, M.D.)

Calcification of the costal cartilages is a process which, while presumed to be a matter of ageing, is frequently found in young persons.

It is generally considered that this deposit is a matter of no consequence. For this reason, perhaps very little progress has been made in determining the factors which cause or are associated with the calcification. Association with various organic diseases, such as pulmonary tuberculosis has been postulated but disproved.

A study of 277 consecutive patients under the age of 40 years has been made. One hundred fifty eight of these were shown by x-ray to have costal cartilage calcification, while 119 did not. In addition to age and sex the following details from the case history were noted: the complaints, the state of nutrition, the basal metabolic rate, the blood calcium, history of menstrual disorders in the women and the final chief diagnosis.

Significant differences between those persons who showed calcium in the costal cartilages and those who did not were found in the number of chief complaints, the history of menstrual disorders, the percentage with obesity and the final chief diagnosis. In the former group there were twice the number of complaints, twice the incidence of obesity and three times the incidence of menstrual disorders. Most remarkable was the fact that the complaints were not due to organic disease five times as often in the calcification group.

It is suggested that premature calcification in the costal cartilages may be evidence of a link between psychiatric and previously unrecognized endocrine disturbances. Further experimental work on young persons showing this phenomenon is needed.

93 PSYCHOSOMATIC PROBLEMS IN A PRIVATE PRACTICE

HOWARD J. RYAN, M.D., AND PHILIP W. MORAN, M.D. (BY INVITATION)
EMPORIA, KAN.

This analysis was made from the office records of two internists in private practice in a community of 15,000 which has a large agricultural farming area. Heavy industry with its attendant physical and psychological problems is not a factor.

To determine the incidence of functional problems 300 consecutive complete office studies were analyzed. Each patient in the study had been subjected to detailed history, complete physical examination and a minimum laboratory and roentgen survey consisting of urine analysis, blood count, sedimenta-

tion rate, and chest fluoroscopy, with chest film if considered necessary. Additional appropriate laboratory or other procedures had been utilized where indicated.

It is fully realized that an analysis of this type cannot be entirely objective, and that the personal equation must enter into the classification of certain patients. As nearly as possible, those patients with demonstrable organic disease which might explain the symptoms were eliminated from the functional or psychosomatic classification. Essential hypertension, peptic ulcer, and urticaria were classified as organic disease in this survey.

The 300 cases comprised 119 men and 181 women.

Of the 300 cases, ninety-two, or 31 per cent, were considered to fall within the functional or psychosomatic classification. These ninety-two cases comprised thirty men and sixty-two women. On the basis of these figures, 25 per cent of all the men studied and 34 per cent of all the women studied could be so classified. Men constituted 40 per cent of the total series and 33 per cent of the functional problems.

An attempt was made to classify the primary complaint of each of these ninety-two patients within an organ system.

SYSTEM	CASES
Circulatory	27
Respiratory	3
Gastrointestinal	21
Urinary	2
Neuromuscular	6
Endocrine	1
Visual	1
Oral (buccal lesions)	1
General (fatigue, tension, headache)	30

A separation of the three major classifications according to sex is as follows:

SYSTEM	TOTAL	MEN	WOMEN
Circulatory	27	12	15
Gastrointestinal	21	5	16
General (fatigue, etc.)	30	9	21

The oldest woman in the functional series was 69 years of age, the youngest, 13. Fifty-five per cent were under 40 years of age which would appear to minimize the climacteric factor in production of symptoms. The oldest man was 67 and the youngest 21.

Analysis of causative factors was difficult. Anxiety, in one guise or another, appeared to be of major importance.

Beneficial results of management coincided closely with the time, patience, and practical common sense devoted to each case.

94 THE EFFECT OF ENTEROGASTRONE CONCENTRATES ON GASTRIC SECRETION IN HUMAN BEINGS

CARL G. MORLOCK, M.D. (BY INVITATION), RICHARD R. FERAYORNI, M.D. (BY INVITATION), AND CHARLES F. CODE, M.D., ROCHESTER, MINN.

We have studied the effect of enterogastone concentrate on the gastric secretory response of human beings to the injection of histamine and to the ingestion of a test meal. An enterogastone concentrate prepared for parenteral administration and one prepared for oral administration were used in this study. The activity of the material prepared for parenteral administration was tested on rats and dogs before it was used in human volunteers.

The enterogastrone preparation given parenterally produced a threefold to fourfold reduction in the volume of gastric juice secreted by rats after pyloric ligation. When the enterogastrone was given intravenously in doses of 100 mg or more to dogs with Heidenhain pouches secreting in response to histamine, pronounced inhibition of acid output uniformly occurred.

Enterogastrone concentrate given intramuscularly to ten human volunteers in doses of 200 mg did not affect significantly the gastric secretory response to the injection of histamine during a double histamine test. Enterogastrone concentrate given to fourteen human volunteers in doses as large as 400 mg intramuscularly and 18 Gm orally did not significantly affect the gastric secretory response to a modified Ewald test meal.

Although the extract of hog's intestinal mucosa used for parenteral administration inhibited gastric secretion in rats and dogs, the immediate conclusion that this was due to enterogastrone was tempered by the fact that toxic reactions sometimes accompanied its use in dogs. Because contaminating substances may have prevented action by enterogastrone in human beings, we do not feel that our results can at this time be interpreted to indicate that pure enterogastrone will be without action in similar tests on human beings.

95 A COMPARISON OF THE TWELVE HOUR NOCTURNAL GASTRIC SECRETION IN UNCOMPLICATED DUODENAL ULCER BEFORE AND AFTER HEALING

ERWIN LEVIN, M.D. (BY INVITATION) JOSEPH B. KIRSNER, M.D. AND
WALTER LINCOLN PALMER, M.D., CHICAGO, ILL.

The twelve hour nocturnal gastric secretion was measured in thirteen patients with duodenal ulcer during a period when the ulcer was easily demonstrable roentgenologically and when typical distress was present. The studies were repeated in the same individuals after medical treatment had led to healing of the ulcer roentgenologically and to the complete subsidence of symptoms.

During the period of active ulcer the volume for the entire group averaged 1047 cc, the free acidity of the total volume averaged 58 clinical units, and the average output of acid 2208 milligrams. After healing of the ulcer, there was no significant change in the average nocturnal gastric secretion: the volume averaging 1,002 cc, the free acidity 54 clinical units and the output of acid 1957 milligrams. A significant decrease after healing was noted in the volume in one patient, in the concentration of acid in two and in the output of acid in one individual. An increase in gastric secretion after healing was observed in a similar number of cases.

The average nocturnal gastric secretion in patients with healed duodenal ulcer is significantly greater than that found in a group of thirty three healthy, normal individuals studied under identical conditions. The secretion of acid in all the patients was continuous and was maintained at a relatively higher level than is seen in normal individuals. In no instance were there periods of anacidity for as long as one hour such as are frequently encountered in normal persons.

The persistence of hypersecretion in the vast majority of cases after healing of duodenal ulcer emphasizes the importance of continued careful antacid therapy in such patients.

96 THE INCIDENCE OF SYMPTOMS AND THE GASTRIC SECRETORY RESPONSE TO HISTAMINE IN PATIENTS WITH AND WITHOUT CHRONIC GASTRITIS

JOHN W FINDLEY, JR, M D (BY INVITATION), JOSEPH B KIRSNER, M D, AND
WALTER LINCOLN PALMER, M D, CHICAGO, ILL

To evaluate more completely the clinical significance of chronic gastritis in patients with gastrointestinal symptoms, a comparative analysis was made of the symptomatology and of the gastric secretory response to histamine among four groups of cases (1) fifty patients with atrophy of the gastric mucosa, (2) fifty with superficial gastritis, (3) fifty with hypertrophic gastritis, and (4) 100 individuals in whom the gastric mucosa appeared normal gastroscopically. The absence of other organic disease was established by normal physical examinations, blood counts, urinalyses, normal proctoscopies, and by normal x-rays of the gastrointestinal tract.

The symptoms, with few exceptions, did not vary significantly among the four groups. The incidence of epigastric pain, the most frequent complaint, ranged from 44 per cent among patients with atrophy to 72 per cent among the normal subjects. The type, location, and pattern of pain were not distinctive for any of the four groups. There were, likewise, no significant differences in the incidence of nausea, vomiting, anorexia, constipation, weight loss, weakness, bad taste, or sore tongue. Diarrhea was described by 22 per cent of patients with atrophy as compared with 4 to 12 per cent for the other groups. The incidence of hematemesis in hypertrophic gastritis was 6 per cent, superficial gastritis, 2 per cent, and none in the remaining groups. A history of melena was encountered in 4 to 6 per cent of patients with gastritis and in one of the normal patients. Numbness or tingling of the extremities was reported by 6 per cent of patients with atrophy of the gastric mucosa and in 0 to 2 per cent of the remaining subjects. The duration of symptoms was essentially the same in all four groups.

Histamine achlorhydria was present in 51 per cent of forty-seven patients with atrophic gastritis, 27 per cent of forty-one with superficial gastritis, 9 per cent of forty-five with hypertrophic gastritis, and 3 per cent of ninety-five normal persons. A quantitative analysis of histamine tests performed in 165 patients indicated, as might be expected, that the smallest amounts of acid were secreted by patients with atrophy of the gastric mucosa, with superficial gastritis next. The output of acid in patients with hypertrophic gastritis, contrary to previous assumptions, did not differ significantly from that of normals.

The present data indicate that chronic gastritis is not an important cause of gastrointestinal symptoms.

97 BLEEDING PEPTIC ULCER, A REPORT OF ONE HUNDRED SIXTY CASES

GEORGE C TURNBULL, M D, AND EDWIN S BRADEN, JR, M D (BY INVITATION)
EVANSTON, ILL

In 1938 a report was made on the eighty patients with bleeding peptic ulcer admitted to Evanston Hospital in the decade 1928 to 1937. The present report is an analysis of the 160 patients with bleeding peptic ulcer admitted in the succeeding decade, 1938 to 1947. It is made to evaluate further trends in management and results thereof.

The results of the present analysis indicate that the starvation (or strict Sippy) regimen is falling into disuse in a general hospital practice. The early use of a relatively liberal and balanced diet has found favor with most attending physicians. The results of this policy are shown by the further reduced time of bleeding, reduced amount of bleeding, lessened emergency surgery, shortened hospital stay, and lowered mortality.

In the present series there is no instance of surgery to control bleeding, and only three had elective surgery, which was done after the hemorrhage and anemia were under control.

It is of interest to note that ascorbic acid blood levels were determined in fifty seven cases of varying clinical background. A few had levels within normal range, but the majority who had distinctly lowered levels of ascorbic acid in the blood showed the most prolonged and severe hemorrhage.

The increased availability of blood in recent years has led to the treatment of some of these patients with repeated transfusions (up to 6,000 cc). In this group there is no conclusive evidence of increased bleeding. On the other hand, there is no conclusive evidence that repeated transfusions are of value in shortening or reducing severity of hemorrhage although they are the outstanding means of therapy for shock.

98 PYLORIC BALANCE IN ILEUS, CONCEPT AND APPLICATION

WILLARD BARTLETT, JR. M.D. St. Louis, Mo.

Ileus is a common clinical picture occurring as a complication of a variety of disorders, and the nature of the primary etiologic agent may become only a matter of speculation unless the patient is seen early in the episode. Mechanical small intestinal obstruction may supervene in peritonitis or vice versa; the factor of depletion of circulating protein by shifts into the peritoneal cavity and the edematous bowel wall occurs in each condition and further impairs intestinal tonus.

In the evaluation of the patient who is seen after several days of illness or in following the development of postoperative complications any additional method of obtaining precise information is valuable. The application of continuous suction to the indwelling nasal catheter is of therapeutic merit but if such decompression is used blindly and without consideration and measurement of the components involved valuable information is not obtained, time is lost and actual harm (dehydration and demineralization of the patient) may be done. When properly employed it affords a unique method of evaluating the degree of impairment of gastrointestinal function and yields data of great diagnostic and prognostic significance.

Quantitative studies begun by the author in 1930 led to the formulation of the term pyloric balance to express the volume and direction of flow of gastrointestinal secretions through the pylorus per day. In ileus prognostic value lies in the fact that the quantity of the negative balance (lost to the body economy) varies characteristically with the nature of the crippling agent. Volumes greater than 1,500 cc are seen in mechanical small intestinal obstruction, rarely exceed 1 liter in peritonitis and are less than 500 cc in the adynamic ileus that follows mere handling of the bowel at operation, particularly in patients with lowered circulating protein. With this factual knowledge the crippling mechanism may be identified more certainly and appropriate treatment selected.

If a mechanical factor is clearly present direct attack on the obstructing agent (band or volvulus) should be made if the general condition of the pa-

tient is good, particularly if the obstruction is jejunal. Enterostomy without exploration remains a most useful method of decompression of obstructed ileal loops, especially in the depleted patient or in those who are intolerant of prolonged nasal intubation. Distal emptying will occur after a few days as spasm and edema of the bowel wall at the site of obstruction subside and as hunking, plastic exudate is absorbed. Nasal catheter suction remains the treatment of choice for ileus in which no extrinsic mechanical factor is present, watch being kept for evidence of an unresolved abscess or infected hematoma which may require drainage.

99 DIAGNOSTIC AND THERAPEUTIC IMPLICATIONS OF ACIDITY VARIATIONS IN THE STIMULATED AND NONSTIMULATED STOMACH

ROBERT B. SCHLESINGER, M.D. (BY INVITATION), LEO L. HARDT, M.D. (BY INVITATION), AND FREDERICK STEIGMANN, M.D., CHICAGO, ILL.

Alvarez and others have pointed out that the determination of the acidity in one gastric aspiration does not give reliable information concerning the gastric acidity status. Similarly, variations in the gastric acidity have been noted during fractional gastric analyses. In the present study we were impressed by marked variations in the acidity in the stimulated and unstimulated stomach not only from day to day but also during each fifteen-minute period and during the time of the experiment, and by their diagnostic and therapeutic implications.

Thirty-five patients with ulcer and four normal controls were tested for free and total acidity at fifteen-minute intervals for one- to two-hour periods daily for five to ten days under standard conditions. Gastric stimulation was produced by 0.1 cc. of histamine diphosphate 1:1,000 solution per 10 kilograms of body weight.

Gastric acidity in nonstimulated ulcer patients varied from 25 to 143 units on successive days during the same period of time (8 to 10 A.M.). In the controls it varied from 0 to 19 units. Following histamine injections the acidity response varied from 6 to 96 units in the patients with ulcer and from 26 to 57 units in the controls. In one patient with gastric ulcer tested at almost weekly intervals, the acidity ranged from 0 to 29 units before and 11 to 62 units following histamine stimulation during a period of three months.

Gastric acidity varies at any given time over a period of days or weeks whether stimulated by histamine or not. These well-known variations may be caused by one of many influences acting upon an individual throughout the day, and should be taken into consideration when the therapeutic effect of any substance is evaluated, inasmuch as otherwise erroneous conclusions can be made by either condemning or approving a certain substance, depending upon the gastric secretory activity on that particular day.

Only prolonged observations on a large number of patients can give a clearer picture concerning the effect of a substance on gastric secretion. Although the daily variations are marked (as seen from the tables), the average obtained from a large sample (over 200 analyses) results in an almost flat curve.

In evaluating substances for ulcer therapy by testing them for their antacid effect, the periodic variations in gastric acidity occurring normally must be carefully considered.

100 GASTRIC ACIDITY RESPONSE DURING THE INTRAVENOUS ADMINISTRATION OF PROTEIN HYDROLYSATES

FREDERICK STEIGMANN, MD MITCHELL ZWIG, MD (BY INVITATION), AND
KARL A. MEYER, MD (BY INVITATION) CHICAGO, ILL.

The gastric secretagogue effects of protein and products of protein digestion when given orally are well known but the effects of intravenously administered protein hydrolysates on gastric acid secretion have been studied by few workers. During an investigation of the clinical uses of protein hydrolysates, such observations on the gastric secretory response were made in a moderately large number of patients who received various types of protein hydrolysates with water or glucose as diluents.

After a control period of gastric secretion obtained during a saline infusion for forty five to sixty minutes, one of the protein hydrolysates was infused at about 72 drops per minute and the gastric aspirations continued for another hour at fifteen minute intervals. Six types of protein hydrolysates (varying according to their preparation and diluent) were studied. Each proteolysate was tested a minimum of eleven and a maximum of twenty four times. 162 tests being performed altogether.

All solutions stimulated gastric acidity to varying degrees and in varying percentages of the patients tested. Complete vagotomy (five patients) and thoracic sympathectomy and splanchicectomy (three patients) did not change the foregoing observations. Plasma infusion caused no rise while 10 per cent dextrose solutions caused a decrease in the gastric acidity.

The increase in gastric acidity during the intravenous infusion of protein hydrolysates may be due to various factors which require further investigation. The same proteolysates in a dextrose solution caused a smaller rise in gastric acidity and in a smaller number of patients. The pH of the solution seemed to be a factor also. Thus the hydrolysates with a pH of 4 gave a higher acidity response than those with a pH of 6.5 to 7.0 (81 to 31 per cent respectively in forty three tests). While the histamine content of these mixtures could be considered the cause of the gastric acid response following their intravenous administration, the results did not bear this out clearly. The hypoglycemia suggested by some observers as a cause for increased gastric secretion was not encountered in our patients.

These observations suggest that various known and some unknown factors may cause increased gastric acidity during protein hydrolysate infusions. In the clinical use of protein hydrolysates therefore one must attempt to eliminate at least the known various factors which possibly increase the gastric acidity, because such an increase may be harmful in some patients.

101 EXPERIENCES WITH NEEDLE BIOPSY OF THE LIVER IN HEPATIC CIRRHOSIS

R. C. COGSWELL, MD (BY INVITATION), F. CLEVELAND, MD (BY INVITATION),
E. A. GALL, MD (BY INVITATION), F. WEISBROD, MD (BY INVITATION), AND
L. SCHIFF, MD CINCINNATI, OHIO

Needle biopsy of the liver has revealed the presence of hepatic cirrhosis in sixty-six patients seen at the Cincinnati General Hospital during the past four and one half years. The cirrhosis was classified as nutritional (alcoholic) in thirty seven, postnecrotic in seventeen, biliary in four and was unclassified in eight. In the course of the clinical study, the following laboratory tests were

performed in most of the cases cephalin-cholesterol flocculation, thymol turbidity, biomsulfalein excretion (5 mg per kilogram of dye, retention in forty-five minutes), and serum bilirubin concentration. In over one-third of the cases total serum protein and albumin/globulin ratios were determined. The clinical diagnosis of cirrhosis was confirmed by the biopsy in fifty-five patients. In the remaining eleven, cirrhosis was first recognized as the result of the liver biopsy.

An attempt was made to correlate the histopathologic changes with the results of the various tests. The morphologic alterations were classified according to the degree of fatty vacuolization, cellular degeneration and necrosis, bile stasis, inflammatory reaction, and fibrosis. In the group of thirty-seven patients with nutritional (alcoholic) cirrhosis such a correlation study has been accomplished. Jaundice or hyperbilirubinemia was present in twenty of these patients, the thymol turbidity was increased in fifteen and normal in twenty, the cephalin-cholesterol flocculation was positive in thirty and negative in seven, biomsulfalein retention was present in twenty-nine and absent in five. Except for more marked fibrosis in the patients with either positive cephalin flocculation tests or abnormal biomsulfalein retention, there was no direct correlation between the results of the tests and the character of the histopathologic changes noted.

102 THE BLOOD AND BONE MARROW IN PATIENTS WITH CIRRHOSIS OF THE LIVER

LAWRENCE BERMAN, MD (BY INVITATION), ARNOLD R AXELROD, MD (BY INVITATION), SAMUEL D JACOBSON, MD, THOMAS N HORAN, MD (BY INVITATION), ELMORE C VONDERHEIDE, MD, AND ELWOOD A SHARP, MD
DETROIT, MICH

The peripheral blood and bone marrow findings in cirrhosis of the liver have been analyzed on the basis of a review of the literature and the authors' study of twenty-five patients with diagnoses verified by biopsy of the liver. The principal blood findings are macrocytic or normocytic anemia with normal or elevated mean corpuscular hemoglobin values, lymphopenia, and thrombocytopenia in the majority of the cases. Anemia may be independent of bleeding, and the severity of the anemia or macrocytosis does not appear to be related to the severity or duration of the liver lesion, although this appears to be true of experimental cirrhosis in rats. Absolute lymphopenia, regardless of the total leucocyte count, is the most constant significant alteration of the leucocyte picture.

The consistent change in the bone marrow is extension of the marrow organ so that active hematopoiesis is found in the shafts of the long bones. Regardless of the presence or absence of bleeding or anemia, the marrow of the sternum is of normal or increased cellularity, with normal or increased erythroidogenesis and megakaryocytopoiesis in most cases.

Even in patients with advanced liver lesions hypocellularity of the marrow is an unusual finding, in spite of peripheral anemia which is often characterized by a lack of signs of accelerated regeneration of red cells.

Macronormoblastic erythropoiesis is seen in patients with macrocytic anemia, but megaloblastic erythropoiesis does not result from hepatic cirrhosis.

The presence of peripheral cytopenias (anemia and thrombocytopenia) in spite of normal or increased formation of erythroblasts and megakaryocytes in the marrow is suggestive of hypersplenism. The well-known involvement of the spleen in patients with hepatic cirrhosis is additional evidence in favor of this view.

In patients with chronic hemorrhage, the blood and sternal marrow pictures are those of iron deficiency anemia although other changes such as lymphopenia and thrombocytopenia tend to persist

The changes described in the blood and bone marrow are not considered pathognomonic of hepatic cirrhosis even though they appear to be characteristic of the disease. The combined blood and sternal marrow study is useful in establishing the diagnosis of cirrhosis of the liver in patients in whom other diseases have obscured its manifestations or in whom historical evidence was absent so that the clinical diagnosis was difficult to make

103 THE ROUTINE USE OF THE SERUM FLOCCULATION REACTION WITH HAYEM'S SOLUTION

EMANUEL E. MANDEL, M.D. AND DELMO A. PARIS, M.D., CHICAGO, ILL.

(INTRODUCED BY HANS POPPER, M.D.)

A serum flocculation test with Hayem's* solution has been described by Gros as being a fine indicator of hepatic disease. The simplicity of his method appeared to justify an attempt at using it as a screening test. A modification of the original Gros test necessitated by apparent shortcomings was employed routinely in a series of 500 patients. The technique consists chiefly in mixing equal volumes of serum and Hayem's solution. Development of a precipitate within twenty-four hours is considered a positive result.

Seventy-two patients had a positive H (Hayem's) test. They may be classified as follows: acute hepatitis five, cirrhosis of liver ten, prolonged obstructive jaundice (two to six months) three, neuro and cardiovascular syphilis, one, syphilitic chancre two, active infectious or rheumatoid arthritis eight, acute rheumatic fever one, severe congestive failure two, chronic lung infections (including pleuritis) fourteen, acute infectious diseases, fourteen, neoplastic diseases, eight, pyonephrosis one, thyrotoxicosis two, and scleroderma, one.

In all cases of this group and in many of the H negative group, one or more of the following tests were carried out: sedimentation rate, cephalin flocculation, thymol turbidity, zinc sulfate turbidity, and Takata-Ara. The incidence of abnormal results of these tests was considerably higher in the H positive than in the H negative group. Likewise, hyperglobulinemia was far more frequent in H positive than in H negative sera. A significant increase in gamma globulin as determined by the Cohn-Wolfson method was found in all of the thirty-five H positive sera in which this determination was performed.

In some instances a positive H reaction was the only pathognomonic sign at the time of the patient's first examination, followed sooner or later by the discovery of the responsible disease (cirrhosis, metastatic neoplasm, pyonephrosis, pleuritis, active tuberculosis). No false positive reaction was encountered. All of these seventy-two patients were seriously ill, even though the initial symptoms did not always betray this fact.

The H negative group of 428 patients included a variety of conditions as they are encountered in the average hospital population. Among them were ten cases of acute hepatitis and three of (recent) obstructive jaundice, but none of cirrhosis of the liver.

The conclusion is warranted that the H test is capable of revealing diseases causing serum protein alterations. Hyperglobulinemia and particularly, increases of gamma globulin appear to be chiefly responsible for a positive reaction.

Mercury bichloride 0.5 sodium sulfate 50 sodium chloride 100 distilled water 100.00

Consequently it may reveal not only a hepatic disorder but also systemic infections and malignant diseases. A negative test does not rule out any such conditions except perhaps cirrhosis of the liver. These findings and the simplicity of the test would favor its adoption as a routine clinical procedure.

104 THE INFLUENCE OF INGESTION OF VARIOUS LIPIDS UPON THE THYMOL TURBIDITY

HANS POPPER, M.D., FREDERICK STEIGMANN, M.D., HATTIE DYNIEWICZ, Ph.D. (BY INVITATION), AND ALVIN DUBIN, M.S. (BY INVITATION), CHICAGO, ILL.

The thymol turbidity depends on the interplay of various factors among which the serum lipids appear the one most easily influenced experimentally. Hence the thymol turbidity was determined in 163 patients with various diseases before and three and six hours after the intake of various lipids. The turbidity rose, in general, after the ingestion of almost every type of lipid, the highest rise being encountered after administration of 50 Gm. of butter. The addition of 6 Gm. of choline to the butter usually enhanced the rise in the thymol turbidity. Choline alone elevated the thymol turbidity significantly less than butter with choline or butter alone. In five patients in whom the elevation of the thymol turbidity after the administration of butter and choline was compared with the rise of the serum phospholipids and total lipids, the slope of the thymol turbidity curve paralleled far more that of the serum phospholipids than that of the total lipids. The same was found in three patients in whom the response of the thymol turbidity, serum phospholipids, and total lipids was determined after the intake of either butter or choline alone. It was therefore concluded that the response of the thymol turbidity to the intake of choline or butter reflects primarily an elevation of the serum phospholipids. This is in keeping with the reported high concentration of phospholipids in the serum precipitate produced by the addition of thymol and by the known relation of choline to the serum phospholipids. The zinc sulfate turbidity—reflecting primarily gamma globulin (Kunkel)—was determined in almost all instances simultaneously with the thymol turbidity, it represents an important supplement to the diagnostic use of the thymol turbidity and is to a much lesser degree influenced by lipid intake.

The alimentary rise of the thymol turbidity was on the average over 3 units in control subjects. It was depressed to a statistically significant degree (to about 1 unit) in infections, carcinoma, cirrhosis, and obstructive jaundice, and also in cardiac and wasting diseases. The smallest response, if any, was noted in gastrointestinal diseases. In acute infectious hepatitis the postprandial rise was almost normal. The response of thymol turbidity to the intake of butter and choline can thus be considered as a simple clinical test of intestinal absorption of lipids, most probably reflecting the phospholipids.

105 COMBINATION OF FLOCCULATION TESTS IN THE DIFFERENTIAL DIAGNOSIS OF JAUNDICE

FREDERICK STEIGMANN, M.D., HANS POPPER, M.D., AND BERNARD H. SHULMAN, M.D. (BY INVITATION), CHICAGO, ILL.

In 455 patients, 262 with jaundice, the cephalin cholesterol flocculation, thymol turbidity, and thymol flocculation were performed, and in almost all of them also the Takata-Ara, colloidal red, Gros (flocculation with Havem's solution), and zinc sulfate turbidity (Kunkel) tests.

Most sensitive in the recognition of liver damage in order of decreasing frequency, were the Gros test the zinc sulfate turbidity, thymol turbidity, cephalin cholesterol flocculation, thymol flocculation, and Takata Ara test.

In general, all flocculation tests were abnormal in a much higher percentage of patients with medical (patent extrahepatic biliary tract) than with surgical (obstructed extrahepatic biliary tract) jaundice. However, the number of false positive or negative tests with each individual test was too high to permit much reliance on the results of individual tests in the differential diagnosis. Purulent hepatitis produced by bacterial infection of the portal triads shows, though surgical in nature, the same results in the flocculation tests as the medical types of hepatitis. However, liver cell damage caused by biliary obstruction alone (biliary hepatitis) reveals as a rule, negative or only slightly positive flocculation tests. If the possibility of a purulent hepatitis which can be recognized clinically by signs of septicemia is considered, the diagnostic value of the individual flocculation tests is somewhat increased. If the results of cephalin flocculation, thymol turbidity, Gros test and zinc sulfate turbidity are dovetailed with each other by bringing them into a system which considers the degree of alteration of these tests, the percentage of those wrongly diagnosed as medical (false positives) was reduced to 35 per cent and of those wrongly diagnosed as surgical (false negatives) to 13 per cent of all jaundice cases.

In the differentiation of cirrhosis from infectious or toxic hepatitis, zinc sulfate turbidity and Gros tests are of particular value; they are highly pathologic in cirrhosis even with only slightly increased cephalin flocculation and thymol turbidity and moderately pathologic in acute hepatitis even if cephalin flocculation and especially thymol turbidity are greatly elevated. The Takata Ara test is positive in cases with highly elevated zinc sulfate turbidity.

A quantitative correlation of the results of several flocculation tests may be useful for the differentiation between medical and surgical jaundice on the one hand and acute and chronic hepatitis (cirrhosis) on the other.

106 INFLUENCE OF ENDOGENOUS AND NUTRITIONAL FACTORS UPON THE PLASMA VITAMIN A ALCOHOL

HANS POPPER, MD, FREDERICK STEIGMANN, MD, HATTIE DANIEWICZ, PHD
(BY INVITATION), AND ALVIN DUBIN, MS (BY INVITATION), CHICAGO, ILL.

The total plasma vitamin A level reflects only vaguely temporary changes in vitamin A nutrition (it is reduced only in prolonged deficiency) and is significantly influenced by endogenous factors for example liver diseases or infections. Vitamin A in plasma and tissues occurs in either the free (alcohol) or the esterified form. Four fifths of the total plasma vitamin A is normally in free form, whereas the liver contains primarily esterified vitamin A.

The question arises as to the influence of nutritional as well as endogenous factors upon the fractions of the total plasma vitamin A. In 276 control subjects and patients suffering from various diseases the vitamin A esters only rarely were decreased below the normal (around 10 μg per 100 cc) but were significantly increased in nephrosis and erratically increased in various illnesses, especially liver diseases. The alcohol fraction, however, was significantly reduced (from about 40 to almost 15 μg per cent per 100 cc) in carcinoma, malnutrition, wasting diseases, infections (such as pneumonia) and liver diseases especially cirrhosis, in which the lowest levels (for example 2 μg per 100 cc) were observed. Under pathologic circumstances the esters may represent even under fasting conditions more than 90 per cent of the total plasma vitamin

A Endogenous hypovitaminemia A, therefore, is caused almost entirely by a reduction of the alcohol fraction, the esters often even being elevated. This effect can be explained by impaired release of vitamin A alcohol from the damaged liver due to inactivation of vitamin A esterase which normally converts the liver vitamin A ester to alcohol. Presence of esterase could be demonstrated in human liver and serum.

Intake of 75,000 units of vitamin A in aqueous or oily menstruum raises the plasma vitamin A esters for several hours. They may then represent in controls 80 per cent of the total vitamin A since the alcohol level does not rise during this period (twelve cases). Prolonged effect on vitamin A nutrition, however, was reflected in the plasma vitamin A alcohol. In eighteen persons who were given alternately for one to two weeks a diet containing less than 100 units of vitamin A daily or a normal diet with daily supplements of 10,000 units vitamin A, the plasma vitamin A alcohol level was, as a rule, significantly higher during the supplemented period than during the vitamin A poor period. A few exceptions found under pathologic conditions require further explanation. The vitamin A esters did not reflect the vitamin A intake, often being elevated during the vitamin A poor period.

It is concluded that both endogenous and general nutritional factors influence primarily the vitamin A alcohol level and that the latter, being independent of postprandial effects, represents a more sensitive index of vitamin A nutrition than the total vitamin A level.

107 STUDIES OF THE INFLUENCE OF OXYQUINOLINE DRUGS ON GROWTH OF ENDAMOEBA HISTOLYTICA AS MEASURED IN BLOOD IODINE LEVELS OF MAN

ALVA A. KNIGHT, M.D., AND JEANNE MILLER, M.A., CHICAGO, ILL.

(INTRODUCED BY ROBERT W. KEETON, M.D.)

In the study of iodine absorption in the oxyquinoline drugs in man, we found blood levels of iodine to be approximately 100 gammas in Anayodin and chiniofon, 400 gammas in Vioform, and 800 gammas in Diodoquin.

We then began the study of growth curves of *Endamoeba histolytica* in mixed bacterial flora in media consisting of equal parts of human serum and egg yolk infusion. Counts of both the amoeba and the bacteria in the inoculum were made, and these counts were repeated in the inoculated media at twelve, twenty-four, forty-eight, seventy-two, and ninety-six hours. The peak growth of *E. histolytica* occurred at forty-eight to seventy-two hours, while the bacteria continued to grow profusely for a longer period without diminution.

The patient was then given one of the oxyquinoline drugs for seven to ten days and the blood again drawn and its iodine content in gammas determined. Culture media of equal parts of serum and egg yolk infusion was again prepared and the inoculations made as before. The counts of *E. histolytica* and bacteria were made at the same time intervals as before. A total of over forty patients was studied.

Inoculated media containing 100 gammas of iodine showed a slow growth of *E. histolytica* continuing to seventy-two and ninety-six hours, but not the continuing rise to forty-eight or seventy-two hours previously shown. Growths became less active as the iodine level rose, and between 250 and 300 gammas no growth beyond forty-eight hours was shown. Levels of 400 to 600 gammas showed a progressively shorter growth period—rarely was any growth present at twenty-four hours.

The bacterial growth was uninfluenced by the varying iodine levels.

Studies in fecal concentrations of iodine have been made on a few patients. Other iodides are being studied in like manner and are to be reported on at a later date.

108 THE CLINICAL EVALUATION OF DUODENAL SUBSTANCE IN CHRONIC ULCERATIVE COLITIS

MICHAEL H. STRFICHER, M.D., CHICAGO, ILL.

Duodenal substance was administered to thirty-five patients who had chronic ulcerative colitis. The dosage used varied from 12 to 48 tablets daily, each $\frac{1}{4}$ Gm. administered uninterruptedly for one year. No other specific medication was used. The patients were on a controlled diet.

Comparative clinical evaluations were made as to the frequency of exacerbations in the disease before and after intake of duodenal substance, frequency of stools, presence of blood in the stools, gain or loss in weight, exaggeration or alleviation in abdominal cramping, and the general well-being of the patients under treatment.

The results obtained in 85 per cent of the patients were very favorable.

1. Exacerbation of the disease was noted in three instances.
2. The majority of the patients gained weight.
3. The majority of the patients felt better and ate better while receiving duodenal substance.
4. Duodenal substance may be considered a very valuable aid in the therapy of chronic ulcerative colitis.

109 THE CYTOLOGIC DIAGNOSIS OF CANCER OF THE STOMACH: PRELIMINARY REPORT

JEROME M. SWARTS, M.D. (BY INVITATION), ARTHUR BERNSTEIN, M.D. (BY INVITATION), ALEX. B. RAGINS, M.D. (BY INVITATION), AND JACOB MEYER, M.D., CHICAGO, ILL.

The need for additional diagnostic methods for the purpose of detecting gastric neoplasms is well known. While the tested techniques of x-ray and gastroscopy are adequate in most cases, the results of these examinations not infrequently are equivocal or negative in the presence of a malignant tumor of the stomach.

The recent application of the cytologic technique in the diagnosis of cancer of the uterus has given impetus to wider application of the method in the diagnosis of neoplasms of the respiratory and genitourinary tracts. This method has been further utilized to a limited degree in the detection of carcinoma of the stomach.

In undertaking this study it was our purpose to evaluate its effectiveness both as an individual test and as a test complementary to roentgenography and gastroscopy in a large general hospital.

The method employed has been that of fasting gastric lavage with physiologic salt solution. The sediment obtained is smeared on glass slides, the smears being relatively thick. The stain which we have found most reliable is LA 36 (Papanicolaou). In addition we have also used the method of formalin fixation and paraffin section, staining the latter with stain LA 36 and with the standard hematoxylin and eosin stains.

All of the patients studied had clinical histories suggesting the possibility of gastric neoplasms. In the beginning we employed thin smears in forty-nine

instances, but because of the paucity of cells, this technique was abandoned. This report is based upon the study of 175 cases employing the thick smear technique. The paraffin section method has been used concomitantly in approximately 150 of these cases. Diagnoses in these cases included (1) carcinoma of the stomach, (2) gastric ulcer, (3) duodenal ulcer, (4) benign gastric neoplasms, and (5) gastritis and a variety of extragastric diseases.

Of the 175 cases, about thirty-five cases of gastric carcinoma are included. We have been able to make definitely positive diagnosis in approximately 35 per cent of these cases. Those cases of carcinoma of the stomach in which we were unable to make a positive cytologic diagnosis were cases in which the smears, because of the presence of debris and poorly preserved cells, allowed no interpretation. The two most important factors which prevent our making a positive diagnosis are (1) gastric retention and (2) the presence of large, necrotic tumors. The other factor is the infiltrating type of tumor without mucosal involvement. The proportion of false positive reports should not exceed 10 per cent, and we feel that this figure will be reduced even further. The results of the paraffin section studies parallel those of the smear study, the hematoxylin and eosin stains seem to be preferable when the former technique is used. In several instances we failed to find tumor cells preoperatively, and washings of the resected specimens also failed to reveal malignant cells.

This is a preliminary report. The series is as yet too small and the method too new to give statistically valid results. In the individual case, however, when other methods of examination give equivocal or negative results, a positive cytologic diagnosis may solve the problem.

110 COMPARATIVE NITROGEN BALANCE STUDIES OF ORAL PROTEIN DERIVATIVES AND NATURAL PROTEIN IN PROTEIN-DEFICIENT PATIENTS

DONALD D. KOZOLL, M.D., AND GORDON MACNEIL, M.D. (BY INVITATION)
CHICAGO, ILL.

Abundant evidence exists proving that oral protein digests are both practical and biologically efficacious. A question which logically arises is, if patients are capable of ingesting a processed protein, what advantages does such a preparation offer over natural protein? A metabolic study in which synthetic and natural proteins are evaluated in the same protein-depleted patient has not to our knowledge, been presented.

The opportunity to conduct such a study on three severely hypoproteinemic and hypoalbuminemic subjects presented itself in the course of a metabolic project designed to determine the relative biologic indices of a preparation of gluten with and without 1 per cent lysine. After having been on a regimen of protein therapy calculated to produce bare nitrogen equilibrium for periods of from thirty-four to fifty-five days, the patients showed no signs of clinical improvement or of regeneration of serum proteins or albumins. The patients were then given gluten with 1 per cent lysine* to the point of tolerance for periods of from eight to ten days, then equivalent amounts of natural proteins such as meat, eggs, and milk, and finally they were allowed diets combining maximal quantities of both. Daily nitrogen analyses of urine, stool, and ingested protein were carried out. Body weight, total serum protein, and serum albumin determinations were made at the beginning and conclusion of each period.

*Provided by Interchemical Corporation

Results—The maximal quantities of gluten with 1 per cent lysine ingestible averaged 22.8, 26, and 28.6 Gm nitrogen per day for patients weighing 44.3, 52.0 and 55 kilograms respectively. This produced positive nitrogen balances of 9.3, 9.4, and 10.9 Gm nitrogen per day respectively.

The maximal quantities of natural protein ingested ran 24.8, 26.5 and 28.6 Gm nitrogen per day in the same order as previously given. The positive nitrogen balances were 7.5, 11.8, and 9.7 Gm nitrogen per day in the order described.

The patients were able to ingest mixtures of the two sources of protein in the average ratio of two parts of the protein derivative to one part natural protein. Accordingly 51.0, 49.7 and 55.8 Gm nitrogen per day, respectively were ingested (on the basis of body weight this was 6 Gm or more protein per kilogram per day). This produced positive nitrogen balances of 18.8, 18.4 and 30.6 Gm nitrogen per day respectively.

Total serum protein concentration increases for all three periods were 1.5, 3.3, and 2.2 Gm per 100 cc respectively. Increases in serum albumin concentration were 1.1, 2.1 and 2.0 Gm per 100 cc respectively.

Gains in body weight of 6.1, 7.0 and 6.3 kilograms, respectively, were noted at the end of the experiment.

Conclusions—

(1) In two out of three protein depleted patients gluten with 1 per cent lysine produced a significantly better nitrogen balance than did similar quantities of natural protein. In a third patient the reverse was true.

(2) Combining a protein derivative with natural protein enabled the patients to ingest considerably more nitrogen than possible with either one alone.

(3) The ingestion of 6 or more grams of protein per kilogram per day was therapeutically feasible.

(4) Significant responses in total serum proteins, serum albumin and body weight were seen.

111 EXPERIENCES WITH A MERCURIAL DIURETIC FOR SUBCUTANEOUS INJECTION

JOSEPH F. BORG, M.D. and DAVID M. CRAIG, M.D. (BY INVITATION)
ST. PAUL, MINN.

A new mercurial diuretic prepared for subcutaneous administration has been tried clinically in office and hospital practice. Thionein is an organomercury compound combined with mercapto acetate forming a mercaptide. It is a readily soluble white powder which is diluted with water to contain 40 mg of mercury per cubic centimeter. Preliminary reports show it to have a low incidence of local or systemic toxicity in animals.

The present report includes observations on thirty patients who have received from 1 to 50 subcutaneous injections of Thionein. The patients had all been under our observation and most of them required frequent intravenous injections of one of the mercurial diuretics for control of congestive failure. Patients were maintained on ammonium chloride in dosage of 4 to 6 Gm daily preceding and during the course of the present observation. Digitalis was continued if the patient was previously digitalized. Changes in the morning weight and also clinical observations of edema and pulmonary congestion were used as criteria of diuretic effect. The dosage was usually 1 cc, but ranged from 0.25 to 2 cc. Following injection, diuresis began in two to six hours and lasted from twelve to forty eight hours. The weight loss was proportional to the

amount of edema and was usually two to five pounds, with extremes of zero to fifteen pounds. Three patients, followed for three months, have maintained a steady edema-free weight by substitution of Thimerin for intravenous mercurials.

The injections have been surprisingly free from local reaction. One patient developed a sore nodule, still present after one month, another complained of local tenderness, lasting one week. About one-third of the patients experienced systemic symptoms, ranging from slight muscle cramps to severe prostration, cramps, and diarrhea, lasting from twelve to seventy-two hours. The more severe reactions were associated with greater urine output, although there was considerable individual variation. Usually subsequent injections, even with comparable diuresis, were attended by lesser or absent reactions. In four patients the use of Thimerin was discontinued because of the severity of the symptoms. We have found Thimerin a satisfactory diuretic for subcutaneous administration in the majority of patients. There is a low incidence of local reactions. Systemic reactions are more frequent than are seen after intravenous mercurials. When these occur, they are related to the degree of diuresis and can usually be prevented by the use of smaller doses.

112 RENAL EXCRETION OF SALICYLATE DURING TREATMENT OF ACUTE RHEUMATIC FEVER

WILLIAM S. HOFFMAN, M.D., AND CATHERINE NOBE, B.S. (BY INVITATION)
CHICAGO, ILL.

Clearance studies were carried out in twelve patients who were convalescing from acute rheumatic fever but were still taking large doses of aspirin (6 to 9 Gm daily). Urine salicylate was partitioned into total salicylate, free salicylate, and salicylurate by the method of P. K. Smith and colleagues. Chloride and creatinine clearances were likewise determined. After these tests the subjects were placed on an alkalinizing regimen with doses of 2 to 3.3 Gm of sodium bicarbonate every six hours for three days in addition to the regular aspirin medication. The clearance tests were then repeated. The urinary pH was noted in both sets of experiments. Plasma salicylate was found to be practically entirely unconjugated and was calculated as if it were all unbound, even though from 60 to 90 per cent has been found by other investigators to be bound to protein. To rule out the effect of alkali on the glomerular filtration rate, the apparent free salicylate clearances were expressed as ratios of salicylate to creatinine clearance ($SA/C \times 100$), as were chloride clearances ($Cl/C \times 100$).

During the initial tests, when the urine pH ranged from 4.98 to 5.99, $SA/C \times 100$ ranged from 0.84 to 2.43, while $Cl/C \times 100$ ranged from 0.45 to 3.16. In other words, the free salicylate ions which were filtered by the glomeruli were reabsorbed by the tubules almost as completely as chloride, if the urine was strongly acid. In the second set of experiments, when the urinary pH ranged from 6.22 to 7.98, $SA/C \times 100$ ranged from 4.6 to 22.8 or from two to eight times as high as when the urine was acid. The true clearance of unbound plasma salicylate would have been three to five times higher than these values. In other words, in the presence of excess sodium ions, free salicylate was cleared almost as well as mannitol. This phenomenon would account for the lowering of plasma salicylate levels when alkali is given.

The ratio of free salicylate to total salicylate in the urine was found to be proportional to the pH of the urine, being as low as 0.10 when the urinary pH

was about 5.0 and as high as 0.66 when the pH was 7.75. Thus alkalinization did not affect the excretion of conjugated salicylates which were apparently already maximally high. In fact, with the absence of detectable amounts of conjugated salicylates in the plasma, it appeared that conjugated salicylates were either formed in the renal tubules or secreted by them like diodrast or hippurates.

Chloride creatinine clearance ratios were not found consistently increased after alkalinization. Since the excretion of chloride is affected by many factors which could not be controlled in these experiments these results are not surprising. Yet the dependence of both chloride and salicylate excretion on the amount of fixed base available for excretion would make it appear that both compete with each other for the available base and that under the conditions of acid urines both are for the most part retained. This might explain the high plasma chloride and relatively low sodium concentrations found during salicylate therapy.

113 THE RECORDING OF OXYGEN SATURATION OF HEMOGLOBIN BY A WHOLE BLOOD OXIMETER AND ITS APPLICATION TO CLINICAL INVESTIGATION

DALE GROOM, M.D., EARL H. WOOD, M.D., AND HOWARD M. ODELL, M.D.
ROCHESTER, MINN.

(INTRODUCED BY H. B. BURCHELL, M.D.)

A photoelectric oximeter has been devised by means of which the degree of oxygen saturation of whole blood can be measured instantaneously and continuously, independent of the total content of hemoglobin with a degree of accuracy sufficient to warrant its use in place of the Van Slyke gasometric analysis procedure in a variety of clinical and research applications.

The method is based primarily on two physical principles: (1) that of measurement of concentration of the chief blood pigments, oxyhemoglobin and reduced hemoglobin, in terms of their transmission of light according to Beer's law and (2) the differential light absorption characteristics of these pigments in two spectral regions.

Whole blood, either in the form of a small sample or in continuous flow is contained in a polythene tube which has an internal volume of 0.5 cc. and is transilluminated by a constant intensity light source. The emergent light is recorded in two selenium barrier layer photoelectric cell circuits, one filtered to pass the red light wave lengths (650 to 750 millimicrons) which are transmitted almost exclusively by oxyhemoglobin, the other filtered to record in the near infrared (750 to 1000 millimicrons) where both oxyhemoglobin and reduced hemoglobin transmit with approximately the same facility. Since the red cell current represents blood concentration of oxyhemoglobin and the infrared cell current that of total hemoglobin, a ratio of red to infrared cell currents constitutes a measure of the relative concentration of the two pigments and therefore of the relative degree of oxygen saturation of the hemoglobin. By empirical calibration of the apparatus against results obtained by the Van Slyke method, absolute values, in terms of percentage of oxygen saturation, can be read directly from a nomogram or from a single calibrated galvanometer scale. The method also lends itself to photographic recording of saturation values synchronously and continuously with recordings of other physiologic variables.

To date this instrument has been utilized chiefly for studies of oxygen saturation of arterial blood and, in diagnostic cardiac catheterization where it allows immediate correlation of roentgenographic, intracardiac pressure and oxygen saturation observations

Accuracy of this photoelectric method has been computed from the results of simultaneous photoelectric and Van Slyke determinations carried out on 131 blood samples ranging in hemoglobin concentration from 13.0 to 25.8 Gm per 100 cc. The standard deviation of the differences between values obtained by the two methods was 1.8 indicated saturation per cent. This implies a 95 per cent likelihood that any saturation determination made by the whole blood oximeter will be within 3.6 per cent saturation of that obtainable by Van Slyke analysis.

114 THE DETERMINATION OF HEMOGLOBIN AS PYRIDINE HEMOCHROMOGEN

A. HUGHES BRYAN, M.D., T. FRANKLIN WILLIAMS, M.A. (BY INVITATION),
AND CELIA R. WEBB, A.B. (BY INVITATION), CHAPEL HILL, N.C.

For use in nutrition surveys a hemoglobin method was sought which would be accurate, reproducible, and convenient to use in field studies, allowing the blood to be analyzed in a central laboratory some hours after collection in the field. Of the many published hemoglobin methods, we selected the pyridine hemochromogen method of Rimington, modified it, and adapted it to the Beckman spectrophotometer and the conditions imposed by field studies.

Method—Ten cubic millimeters of blood measured in a calibrated Sahli type pipette are discharged into 1 cc of distilled water in a tube calibrated to contain 5 cc. The resulting hemolyzed blood is allowed to stand at room temperature twenty-four hours before analysis.

The pyridine hydrosulfite reagent is prepared fresh for each batch of analyses as follows. Five grams of sodium hydrosulfite powder is dissolved in approximately 80 cc of N/10 sodium hydroxide. The solution is filtered, 5 cc of pyridine are added, and the combined reagent diluted to 100 cc with N/10 sodium hydroxide.

To the hemolyzed blood are added 0.5 cc of pyridine hydrosulfite reagent and 1 cc of N/5 sodium hydroxide, and the reaction mixture is diluted to 5 cc with N/10 sodium hydroxide. The tube is shaken after each addition and foaming can be dispelled by the use of one drop of n-butyl alcohol. The density is determined in the Beckman spectrophotometer after ten to sixty minutes at 558 to 560 $m\mu$. Pyridine hemochromogen has a very sharp absorption peak in the neighborhood of 558 to 562 $m\mu$. For accurate work it is necessary to determine the point of maximum absorption for each set of determinations. The hemoglobin content of the blood is obtained from a calibration curve prepared by submitting to the foregoing procedure bloods whose hemoglobin content was determined by analysis for iron. A straight line relationship exists between hemoglobin content and density of pyridine hemochromogen.

We have investigated the influence of the following variables: (1) proportions of sodium hydrosulfite and pyridine in the reaction mixture; (2) effect of the order of adding the reagents; (3) change of absorption with time after adding the reagents; and (4) effect of the time of standing of the hemolyzed blood before addition of the reagents. The conditions described appear to give the most satisfactory and reproducible results. Preliminary work indicates that the error in repeated single determinations on the same blood is less than ± 3 per cent.

115 THE CELLULAR COMPOSITION OF THE BONE MARROW IN NORMAL INFANTS AND CHILDREN

KURT GLASER, MD (BY INVITATION), HENRY G. PONCHER, MD, AND
LOUIS R. LAMARZI, MD, CHICAGO, ILL.

Extensive reviews of the literature on the cellular composition of the bone marrow in children have shown the lack of information available on this subject and have expressed the need for further investigation.

This study covers 138 steril marrow punctures on normal individuals from birth to 19 years of age. There was very little if any variation by age found in the cell counts of individuals ranging in age from 1 to 19 years. The findings of the cell counts of this age group were therefore used to establish normal average values for the cellular distribution of the bone marrow (myeloblasts, 1.23 per cent, leucoblasts, 1.44 per cent, promyelocytes, 1.8 per cent, myelocytes, 3.46 per cent, metamyelocytes, 36.05 per cent, polymorphonuclear cells, 12.9 per cent, eosinophiles, 3.58 per cent, mononuclear cells, 0.47 per cent, basophilic normoblasts, 1.69 per cent, polychromatic normoblasts, 18.2 per cent, orthochromatic normoblasts, 2.72 per cent).

Cell counts on infants less than 1 year and particularly less than 1 month old showed wide and constant variations with age. The number of nucleated red cells during the first and second days of life approximated those established as normal averages (23.12 per cent). From then up to the fifteenth day there was a marked decrease, followed in turn by an increase to average values. Lower figures were again recorded during the third to fifth months. Among the individual cells of this series the polychromatic normoblasts showed variations identical to those of the total red cell group. Mononuclear cells and basophilic and orthochromatic normoblasts showed similar findings but the fluctuations in number became less marked and statistically less significant with the smaller number of cells. Over the entire span of nineteen years there seemed to be a tendency for the younger cells to decrease in number with progressing age and for the older cells to increase during the same period. This variation in percentage was minimal yet it occurred with remarkable consistency.

The observations on the myeloid series likewise brought strong and constant changes during the first month of life with less significant variations during later months and years. The values for the first and second days of life closely approached the average figures (60.59 per cent). The following days we saw a marked increase in number of myeloid cells with a drop around the twentieth day, followed by a rise to average figures by the end of the first month. From then on there was little deviation from the average up to the end of the observation period (nineteen years). As to the individual cells in this group the metamyelocytes which form the largest part of the series showed the same pattern as the total group. The smaller groups of the myeloid series showed findings similar to those of the total group but again the variations were not as marked because these cells occurred in much smaller numbers. In considering the total period of observation there seemed to be again a tendency for the number of younger forms to decrease and for the number of older forms to increase.

The myeloid erythroid ratio showed during the first and second days figures close to the established average (2.94) followed by a sharp rise up to the end of the second week (14.5), when the values again fell reaching the average at the

All cells showing more than kidney shaped indentation of their nucleus were placed among the metamyelocytes thus producing relatively low values for the myelocyte.

To date this instrument has been utilized chiefly for studies of oxygen saturation of arterial blood and, in diagnostic cardiac catheterization where it allows immediate correlation of roentgenographic, intracardiac pressure and oxygen saturation observations

Accuracy of this photoelectric method has been computed from the results of simultaneous photoelectric and Van Slyke determinations carried out on 131 blood samples ranging in hemoglobin concentration from 13.0 to 25.8 Gm per 100 cc. The standard deviation of the differences between values obtained by the two methods was 1.8 indicated saturation per cent, this implies a 95 per cent likelihood that any saturation determination made by the whole blood oximeter will be within 3.6 per cent saturation of that obtainable by Van Slyke analysis

114 THE DETERMINATION OF HEMOGLOBIN AS PYRIDINE HEMOCHROMOGEN

A. HUGHES BRYAN, M.D., T. FRANKLIN WILLIAMS, M.A. (BY INVITATION),
AND CELIA R. WEBB, A.B. (BY INVITATION), CHAPEL HILL, N.C.

For use in nutrition surveys a hemoglobin method was sought which would be accurate, reproducible, and convenient to use in field studies, allowing the blood to be analyzed in a central laboratory some hours after collection in the field. Of the many published hemoglobin methods, we selected the pyridine hemochromogen method of Rimington, modified it, and adapted it to the Beckman spectrophotometer and the conditions imposed by field studies.

Method—Ten cubic millimeters of blood measured in a calibrated Sahlb type pipette are discharged into 1 cc of distilled water in a tube calibrated to contain 5 cc. The resulting hemolyzed blood is allowed to stand at room temperature twenty-four hours before analysis.

The pyridine hydrosulfite reagent is prepared fresh for each batch of analyses as follows. Five grams of sodium hydrosulfite powder is dissolved in approximately 80 cc of N/10 sodium hydroxide. The solution is filtered, 5 cc of pyridine are added, and the combined reagent diluted to 100 cc with N/10 sodium hydroxide.

To the hemolyzed blood are added 0.5 cc of pyridine hydrosulfite reagent and 1 cc of N/5 sodium hydroxide, and the reaction mixture is diluted to 5 cc with N/10 sodium hydroxide. The tube is shaken after each addition and foam can be dispelled by the use of one drop of n-butyl alcohol. The density is determined in the Beckman spectrophotometer after ten to sixty minutes at 558 to 560 $m\mu$. Pyridine hemochromogen has a very sharp absorption peak in the neighborhood of 558 to 562 $m\mu$. For accurate work it is necessary to determine the point of maximum absorption for each set of determinations. The hemoglobin content of the blood is obtained from a calibration curve prepared by submitting to the foregoing procedure bloods whose hemoglobin content was determined by analysis for iron. A straight line relationship exists between hemoglobin content and density of pyridine hemochromogen.

We have investigated the influence of the following variables: (1) proportions of sodium hydrosulfite and pyridine in the reaction mixture, (2) effect of the order of adding the reagents, (3) change of absorption with time after adding the reagents, and (4) effect of the time of standing of the hemolyzed blood before addition of the reagents. The conditions described appear to give the most satisfactory and reproducible results. Preliminary work indicates that the error in repeated single determinations on the same blood is less than ± 3 per cent.

karyocytes is observed in some cases of Hodgkin's disease. These cells are not specific for this reason. These "lymphoid" megakaryocytes may produce atypical forms of platelets. (3) Reed Sternberg cells were not seen in sternal aspiration material nor in the histologic sections of bone marrow particles from such material. Evidence is presented to show that the giant cells of Hodgkin's granuloma are not similar nor related to bone marrow megakaryocytes. (4) The finding of increased numbers of normal or atypical plasma cells, eosinophiles, and reticular cells is neither a constant nor a specific pattern of the bone marrow in Hodgkin's disease. Eosinophilia of the bone marrow cannot be correlated with the peripheral blood eosinophilia. (5) The accurate diagnosis of the disease is established only by the finding of the specific pleomorphic lesion of Hodgkin's granuloma. This is best observed in the histologic section of an involved lymph node. The finding of any one cell or group of cells in sternal aspirated bone marrow films is insufficient evidence for the diagnosis of Hodgkin's disease.

117 ANEMIA OF PREGNANCY TREATED WITH MOLYBDENUM IRON COMPLEX

WILLIAM J. DIECKMANN, M.D. (BY INVITATION), HAROLD D. PRIDDLE, M.D. (BY INVITATION), ROSE TURNER, B.A. (BY INVITATION) AND BETTY TREPTOW (BY INVITATION), CHICAGO, ILL.

Four and six tenths per cent of our pregnant patients have a hemoglobin concentration less than 10 grams per 100 ml. but if the nonpregnant standard of 12 grams is used 39 per cent are anemic. We believe that the lower limit of the hemoglobin concentration between the twelfth and thirty-sixth weeks is 10 grams and from then to term is 10.5 grams. Up to twelve weeks antepartum and by six weeks post partum the lower limit is the normal nonpregnant limit or 12 grams of hemoglobin. All patients are screened by a hematocrit determination every three months at term and again at six weeks and six months post partum. Any patients with hematocrits less than 37 for the nonpregnant or early pregnant or less than 30 between the twelfth and thirty-sixth weeks or less than 32 between thirty-six weeks and term have a hemoglobin determination, an erythrocyte count and the various indices calculated.

Treatment with ferrous and ferric iron alone or with various vitamin combinations did not cause a significant increase in the rate of hemoglobin formation. A molybdenum iron complex has resulted in a rapid increase in hemoglobin concentration. If this does not occur within three weeks then more extensive studies should be made to determine the cause of the anemia.

118 OBSERVATIONS ON THE TREATMENT OF ACUTE LEUCEMIAS WITH ANALOGUES OF FOLIC ACID

W. JACOBSON, M.D., WILLIAM C. LEVIN, M.D. AND GORDON HOLT, M.D.
GALVESTON, TEXAS

(INTRODUCED BY RAYMOND GREGORY, M.D.)

Ten patients belonging to the group with acute leucemia have been treated with Aminopterin (4-amino-pteroylglutamic acid) or Methopterin (10-methyl-pteroylglutamic acid). Acute lymphocytic leucemia (leucosarcoma) was the diagnosis in seven instances and acute monoblastic leucemia in three. Eight patients were children and two were adults.

In general the patients were treated with 2 mg of the compound, administered intramuscularly, on alternate days. Some patients, receiving Methopterin, had the dosages increased to 2 mg daily. Blood transfusions and antibiotics were administered when indicated.

Patients Treated With Aminopterin—Three patients received Aminopterin only, a fourth patient received Aminopterin following an initial period on Methopterin. All four developed evidences of toxic reactions as manifested by stomatitis, macular rash, and marked depression of bone marrow activity. One of this group showed some clinical and hematologic improvement. One patient has died, and the remaining two have failed to show a definite response.

Patients Treated With Methopterin—Methopterin was given to six patients and a seventh received Methopterin but later was treated with Aminopterin. Of these seven patients, two died before the drug had a chance to act. Of the remainder, none developed manifestations of toxic symptoms in contrast to the patients treated with Aminopterin. One patient has developed a very conspicuous clinical and hematologic remission with a reversal of the marrow to a nearly normal picture. Another patient improved while receiving Methopterin but her condition deteriorated when subsequently receiving Aminopterin. Three patients have so far shown no improvement but are still under treatment.

The impression has been gained that Methopterin is superior to Aminopterin in the treatment of acute leucemias, especially in view of its lower toxicity.

119 TREATMENT OF ACUTE LEUCEMIA WITH AMINOPTERIN (4-AMINO-PTEROYLGLUTAMIC ACID)

MEYER PIERCE, M D (BY INVITATION), AND HOWARD ALT, M D, CHICAGO, ILL

Remissions characterized by clinical and hematologic improvement and a return of the marrow pattern to normal in acute leucemias treated with Aminopterin were reported by Faiber and co-workers, in the spring of 1948. The duration of treatment in this preliminary report was of three months or less. This report deals with our experience in the treatment of eleven patients with acute leucemia since May 1, 1948.

The action of Aminopterin is not clearly understood. Faiber observed certain pteroylglutamic conjugate, notably Teropterin and Diopterin, induced an accelerating effect on leucemic tissue. The search for an antagonist drug led to the synthesis of Aminopterin, this product caused a rapid fall in the total blood leucocytes, a reduction in the size of the hematopoietic organs, and aplasia of the marrow.

In our series there were nine children under 10 years of age, one adolescent 13 years of age, and one adult, 66 years of age. All but one had acute untreated leucemia. The duration of the disease prior to treatment was less than one month in ten patients. The drug was administered intramuscularly. The daily dose was adjusted to the age and weight of the patient and varied from 25 to 1 mg in the children and from 1 to 2 mg in adults. Daily administration was continued until clinical and hematologic effects were obtained, thereafter treatment was given four to five times a week until toxic manifestations developed. Transfusions were used to support the anemia. Hematologic effects were followed by serial blood and bone marrow studies. The duration of treatment has extended more than four months in four cases, two months in three, one month in two, and less than one week in two. Of eleven patients treated, eight

are still living, three are dead. Of the eight living patients, five sustained remission three did not. Of the three patients who died one was treated in the terminal phase and one succumbed to cerebral hemorrhage one was the adult. In the five patients in whom complete remissions were obtained, the duration of the clinical and hematologic improvement lasted for more than six weeks in two instances, after which some degree of enlargement of the hematopoietic organ and/or return to the leucemic marrow pattern recurred. Both of these patients are still living. In three cases, the duration of the remission is less than a month. Of the three living patients who showed no remission two were treated continuously four months and one for three weeks.

The remissions were initiated in each instance by a fall in the total number of blasts in the peripheral blood, and a rapid reduction in the size of the hematopoietic organs. The effects occurred within ten to twenty days after instituting treatment. Hyperpyrexia abdominal tenderness and severe hemorrhagic diatheses were often encountered. In all instances a severe aplasia of the marrow accompanied these signs. The total dose of Aminopterin administered before signs of marrow aplasia developed varied from 2.5 to 20 mg. The drug was discontinued when aplasia developed. Following the aplastic stage the total leucocyte count rose gradually followed by a rise in the reticulocytes, erythrocytes and platelet levels. Granulopoiesis returned in the bone marrow within five to ten days. During the period of active marrow granulopoiesis, clinical improvement was dramatic and evidenced by a drop in the temperature curve and general appearance of good health. Treatment was resumed as soon as granulopoiesis was reestablished. Stomatitis developed in seven patients under prolonged treatment. In the two under treatment for four months who sustained a complete remission relapse of the symptoms occurred after six weeks and the clinical course has been subacute. Relapse was initiated by increase in size of the peripheral lymph nodes and spleen, a rising white count and recurrence of the leucemic marrow pattern. Under continued treatment reduction in the hematopoietic organs was obtained again. However the bone marrow has remained leucemic. In spite of the marrow involvement the red count hemoglobin and platelet values remained normal since the initial remission, a period now of more than three months. In the three patients under continuous therapy for four months the clinical course has been subacute and organ involvement has been minimal but no measurable improvement in the marrow pattern has been noted on repeated examinations.

Summary—Of eleven patients with acute leucemia treated since May 1, 1948, remissions have been obtained in five instances. The remissions have been characterized by a severe marrow aplasia followed by a rapid regeneration. Remissions are not sustained. Whether the use of this product will significantly change the course of the disease remains to be proved.

120 TREATMENT OF CHRONIC LEUCEMIA WITH A FOLIC ACID ANTAGONIST

LAWRENCE BERNAN, M.D. (BY INVITATION) ARNOLD R. AXELROD, M.D.
(BY INVITATION), ELMORE C. VONDERHEIDE, M.D. AND
ELWOOD A. SHARP, M.D., DETROIT, MICH.

Previous reports on the use of pteroylglutamic acid antagonists in man have dealt primarily with the treatment of acute leucemia. This study is based on observations of the effect of the folic acid antagonist 4-amino pteroylglutamic acid* in nine patients with chronic leucemia. One of the patients having my

*-4-[(4-aminino-6-pterilyl)-methyl]-amino)-benzo]-glutamic acid

elogenous leucemia received two series of treatments. The drug was taken orally, in daily doses ranging from 1.25 to 7.5 mg over periods from six to twenty-five days. Results are shown in Tables I and II.

TABLE I LEUCOCYTE COUNTS IN PATIENTS WITH MYELOGENOUS LEUCEMIA BEFORE AND AFTER TREATMENT

CASE	TOTAL W B C PER C MM	STEM CELLS PER C MM	IMMATURE GRANULO CYTES PER C MM	MATURE GRANULO CYTES PER C MM	TOTAL DOSE IN MG
1a	300,000	14,280	121,200	109,000	0

4	231,000	26,240	6,644	198,100	0
	180,500	8,570	7,876	164,000	50

Stem cells in both myelogenous and lymphatic leucemia and immature granulocytes in myelogenous leucemia decreased in number, but platelet and erythrocyte counts were variable. Usually mature granulocytes decreased in number during treatment, but lymphocytes of mature type were not affected. Progressive falls in total leucocyte counts occurred for as long as ten days after treatment was stopped.

The most important morphologic effects included the appearance of small numbers of megaloblasts in material aspirated from the sternal marrow. The cells were indistinguishable from those characterizing erythropoiesis in Addisonian pernicious anemia in relapse. They were seen after approximately 100 mg of the medication had been ingested over periods from six to twenty-four days.

In two patients with lymphatic leucemia there were decreases in the sizes of lymph nodes. The hematologic effects of therapy were temporary and never completely adequate because treatment had to be stopped when toxic signs appeared.

The toxic effects, in the order of appearance, included pharyngitis, stomatitis, sore tongue, crampy abdominal pain sometimes associated with diarrhea, dermatitis, and alopecia. Usually pharyngitis first appeared within a few days before or after significant changes in the leucocyte counts were noted. The

total dosage of the drug which produced toxic effects varied from 30 to 75 mg, although one patient received 105 mg without experiencing such signs. There was evidence that when small doses are used initially, a larger cumulative dose can be tolerated before toxic symptoms appear.

Autopsies on two patients who expired shortly after therapy was stopped revealed no changes which could be attributed to the medication.

Although 4-amino pteroylglutamic acid had a definite hematologic effect there was no subjective improvement in any of the patients. The use of the drug in chronic leukemia is limited by the early development of toxic phenomena. Further studies with related compounds are warranted.

121 EFFECT OF ANTIFOLIC ACID DERIVATIVES ON PATIENTS WITH FAR-ADVANCED CARCINOMATOSIS

SAMUEL G. TAYLOR, III, M.D., DANLEY SLAUGHTER, M.D. (BY INVITATION)
FREDERICK W. PRESTON, M.D. (BY INVITATION), JOSEPH CRUMRINE, M.D.
(BY INVITATION) AND GEORGE HASS, M.D., CHICAGO, ILL.

Observations were made on thirty-five patients with far advanced carcinomatosis given pteroylglutamic acid (Teropterin) intramuscularly daily for from two weeks to twelve months. The dose varied from 20 mg daily to 50 mg b.i.d. The following diseases were treated: two epidermoid carcinomas, one carcinoma of the pancreas, three mixed tumors of the parotid, three adenocarcinomas of the cecum, two carcinomas of the colon, five carcinomas of the breast, three transitional cell carcinomas of the bladder, one thymic carcinoma, two bronchogenic carcinomas, one adenocarcinoma of the rectum with carcinoid of the ileum, two carcinomas of the ovary, one epithelioma of the penis, one hypernephroma, one neurofibrosarcoma, one lymphosarcoma, one fibrosarcoma of the orbit, two melanosarcomas, one Ewing's sarcoma, two unclassified malignant bone tumors.

No patients showed any evidence of toxic reactions to the drug even with very large doses. No change in the expected course of the disease was noted in thirty-four of the thirty-five patients given the drug. We were unable to demonstrate any beneficial effects attributable to administration of the drug in these patients.

One patient with pulmonary metastases from a carcinoma of the breast showed roentgenographic evidence of incomplete regression of the metastatic nodules after three months of daily injections of 40 mg pteroylglutamic acid. Though the metastatic nodules persist, there has been no increase in their size five months following cessation of administration of the drug.

Autopsies were performed in twelve instances. No specific effect of the drug on tumors could be demonstrated microscopically.

Twelve patients with malignant disease were given 4-amino pteroylglutamic acid (Aminopterin). The following diseases were treated: one mycosis fungoides, nine carcinomas of the female breast, one adenocarcinoma of the ovary, one melanosarcoma.

Most patients developed ulcerative lesions in the buccal, vaginal or rectal mucosa during therapy. Granulocytopenia occurred in two patients and a fatal pancytopenia developed in one. This patient also had multiple ulcerations of the gastrointestinal tract. Stomatitis and vaginitis usually preceded granulocytopenia. The appearance of toxic reactions frequently necessitated omission

of the drug Stomatitis and leucopenia developed in one elderly patient after two daily injections of 1 mg of 4-amino pteroylglutamic acid

An arrest of rapidly progressive neurological changes and roentgenographic evidence of marked regression in the pulmonary lesions have been noted in one patient with metastatic carcinoma of the breast. Marked regression of regional metastases was noted in one other patient with metastatic mammary cancer. However, both patients experienced severe toxic reactions to the drug.

It is concluded that pteroylglutamic acid in the doses given are probably of no value in the treatment of the types of malignancy stated in the foregoing.

No conclusion can yet be drawn on the effect of 4-amino pteroylglutamic acid on malignancy. However, the dramatic response of one patient necessitates further careful observations despite the dangerous toxic side effects.

122 EFFECT OF VITAMIN B₁₂ ON THE HEMATOPOIETIC AND NERVOUS SYSTEMS IN ADDISONIAN PERNICIOUS ANEMIA

B E HALL, M D, AND D C CAMPBELL, M D (BY INVITATION),
ROCHESTER, MINN

The effect of vitamin B₁₂ in six patients having classical Addisonian pernicious anemia has been studied. In four of the six patients the diagnosis of pernicious anemia had not been established previously. The remaining two patients had had short courses of treatment with parenteral liver extracts four and three years, respectively, prior to admission to the Clinic. All six patients were in severe relapse. Reticulocyte peaks were noted four to seven days after the institution of therapy and were followed by a rise in erythrocyte counts which reached normal levels in from four to six weeks. Serial aspirations of the bone marrow revealed complete conversion from megaloblastic to normoblastic regeneration in from forty-eight to ninety hours after administration of B₁₂. Lantern slides in color will be used to depict the serial changes in the marrow.

Excellent hematologic responses were obtained with doses of 25 µg of vitamin B₁₂ administered at weekly intervals intramuscularly. Some evidence was obtained to indicate that intervals longer than one week between injections were not always accompanied by a maximal rise in erythrocytes. In one case an initial dose of 6 µg was not followed by a maximal reticulocyte response. An interesting observation was the development of hypochromasia in the erythrocytes of two of the six patients during the period of rise in erythrocyte levels. The significance of this observation is not clearly understood and needs further study.

Four of the six patients had glossitis prior to the institution of therapy. In all four the glossitis improved after treatment was begun and eventually disappeared. Four of the six patients also had definite evidence of subacute combined degeneration of the spinal cord. One patient showed no improvement symptomatically or objectively after receiving 100 µg of vitamin B₁₂ over a period of sixty-two days. A second patient showed remarkable improvement after receiving 75 µg over a period of thirty-three days. The remaining two patients have not been observed long enough to permit conclusions to be drawn. It should be emphasized, however, that prolonged observation over a period of many months will be necessary before it will be possible to determine whether or not vitamin B₁₂ therapy will protect permanently the central and peripheral nervous systems in pernicious anemia.

123 ESSENTIALITY OF BOTH THE ANTI-*PERNICIOUS* ANEMIA FACTOR OF LIVER AND PTEROYL-GLUTAMIC ACID FOR HEMATOPOIESIS IN SWINE

ROBERT W. HEINLE, M.D., ARNOLD D. WELCH, M.D., AND JACK A. PRITCHARD,
M.D. (BY INVITATION) CLEVELAND, OHIO

Macrocytic anemia with megaloblastic hyperplasia of the marrow was induced in swine by use of a diet essentially free of extrinsic factor and pteroyl glutamic acid (PGA) and containing a crude PGA antagonist and succinyl sulfathiazole.

One pig thus rendered anemic responded incompletely to one dose of PGA free liver extract (15 units) but two months later failed to respond to ten successive daily doses of 15 units each. Four 15 mg doses of PGA then produced an excellent hematologic response.

Another pig failed to respond to five daily doses of 200 Gm of crude casein, used as a source of extrinsic factor. In a second period ten minute daily doses (0.05 mg each) of PGA caused only a small reticulocyte response. In a third period however five daily doses of 200 Gm of crude casein produced a secondary reticulocytosis and a more complete hematologic response.

The findings indicate that a dual deficiency involving PGA and the anti-*pernicious* anemia (APA) factor was produced. In the first pig it is suggested that the first administration of liver extract produced a small response because PGA was not completely absent while the second administration of liver extract was ineffective because the animal was now devoid of functional PGA. Whether a deficiency of APA factor had also been re-established cannot be stated, but failure to respond to liver extract indicates that the PGA deficiency was, by itself, capable of preventing hematopoiesis. In the second pig it is suggested that extrinsic factor was ineffective until a catalytic amount of PGA was made available.

A third anemic animal responded twice to single doses of 1 mg of PGA given at monthly intervals. However a third dose given after another month failed to elicit a significant response. A single dose of 100 units of purified liver extract produced a good reticulocytosis and a partial hematologic remission. However this restored the ability to respond to PGA as indicated by a good reticulocyte response following a fourth injection of 1 mg.

The results in this animal indicate that deficiencies of PGA and of the APA factor were produced. When the deficiency of APA factor became sufficiently profound PGA was unable to induce hematopoiesis. With removal of the deficiency of the APA factor with a resultant partial remission PGA again became hematopoietically active.

It may be concluded that under the conditions of these experiments neither the APA factor nor PGA can function hematopoietically in the absence of the other and that both substances are essential to the processes involved in the maturation of erythrocytes.

124 FURTHER STUDIES ON THE EFFECT OF URETHANE ON LEUCEMIA

PAUL L. BEDINGER, M.D., CHICAGO, ILL.
(INTRODUCED BY LOUIS R. LIMARZI, M.D.)

Last year, before this Society we reported the effect of urethane in leukemia on experience gained with thirty five cases. We have now studied its effect in a total of eighty five cases. Of these leucemias 30 were acute, 3 were

acute monocytic (Naegeli type), 2 were subacute myelocytic, 2 were subacute lymphocytic, 34 were chronic lymphocytic, and 12 were chronic myelocytic. One patient with lymphosarcoma of the skin and one with myeloid metaplasia of the spleen were also observed.

In general, our later observations bear out those previously reported. The most consistent results in using urethane may be expected in those individuals having the chronic myelocytic type. The white blood count may be brought to a normal level and, except for minor fluctuations, may be maintained there as long as a proper dose is given. If the drug is stopped, the count steadily and rapidly rises; only to drop again with institution of urethane therapy. The red blood cell and hemoglobin values are improved during this treatment.

In chronic lymphocytic leucemia the results in over 80 per cent of our series are good as concerns the lowering of the white blood count. It appears that in some individuals larger doses than can be tolerated are needed for producing the desired effect.

The results in the use of urethane in acute leucemia are the least striking. Although one observed occasionally what appears initially to be a dramatic fall in the white count, the patient either succumbs at this level or has an equally sudden rise to even higher than pretreatment levels before death. We have observed in two of our patients a temporary complete bone marrow remission to normal. However, this effect was not maintained.

There is little effect of urethane on the size of the lymph nodes or spleen in lymphocytic leucemia. As a matter of fact, in one patient with chronic lymphocytic leucemia the glands actually increased in size. Our usual daily dose has been from $\frac{1}{2}$ to 3 Gm orally. Some of our patients have been maintained for eighteen months on the drug, with a total of over 5,000 Gm being administered. At this dosage level no toxic effects, other than weight loss, drowsiness and loss of appetite, have been observed in the living. No tissue changes have been observed from the drug as seen at autopsy. Care should be taken in the intravenous administration of urethane as we have observed a fatality when it was given in this manner.

125 CLINICAL OBSERVATIONS WITH METHYL-BIS (B-CHLOROETHYL) AMINE HYDROCHLORIDE

TIBOR J. GREENWALT, M.D., and ANTHONY J. GRUENINGER, M.D.
MILWAUKEE, WIS.

(INTRODUCED BY MAURICE HARDGROVE, M.D.)

Twenty-four patients have been treated with methyl-bis (B-chloroethyl) amine hydrochloride since November, 1946. The recommended course of treatment consisted of 0.1 mg per kilogram of body weight given daily for four days.

There were twelve patients with Hodgkin's disease proved by biopsy. Seven of these patients were x-ray resistant. Four of the group have died. The average duration of life after starting therapy was eight months (range, one to thirteen months). The other three are still living two to six months after treatment. In five additional patients nitrogen mustard was used as the initial form of therapy. In three of these the beneficial effect was short lived. In the other two the results were more satisfactory. One remained in remission for six months and had two courses of the alkyl amine. Later x-ray therapy was instituted. The other has been in complete remission for nine months and has received three courses of therapy. Two of the five have died. Both were given

x ray therapy after failure of response to mustard. The average duration of disease by history in the six patients who have died was 7.4 years (range, six months to twenty years). The average duration of disease in the six living patients is 15 years at present. It appears that the methyl bis (B-chloroethyl) amine is of value in treating x-ray resistant cases of Hodgkin's disease. It offers no advantages as an initial form of therapy.

Two patients with lymphosarcoma and two with giant follicle lymphoma were given nitrogen mustard. One of each of these had a partial, unsatisfactory remission. One in each category is still in remission nine months after a single course.

One patient with chronic lymphocytic leucemia, one with chronic myelocytic leucemia, and one with polycythemia vera were treated with partial and brief response.

Two patients with squamous cell bronchiogenic and one with small cell adenocarcinoma of the lung, one with squamous cell carcinoma of the floor of the mouth, and one with malignant melanoma of the choroid were treated with but slight effect.

126 THE USE OF RADIOARSENIC (As^{76}) IN THE TREATMENT OF LEUCEMIA AND ALLIED DISORDERS OF THE HEMATOPOIETIC TISSUES

MATTHEW H. BLOCK, M.D. (BY INVITATION), LEON O. JACOBSON, M.D.
WILLIAM B. NEAL, JR., M.D. (BY INVITATION), AND TAYLOR
R. SMITH, M.D. (BY INVITATION), CHICAGO, ILL.

Nineteen patients with tumors of the hematopoietic system have been given As^{76} prepared by pile irradiation of arsenic trioxide and cacodylic acid. Arsenic 76 has a half life of 26.8 hours and energetic beta and gamma radiations. Doses of As^{76} ranged from 1 to 80 millicuries with 3 to 10 mg. of stable arsenic and were administered intravenously as the trioxide. Preliminary studies indicated that each millicurie was approximately equivalent to one roentgen of total body radiation. In four previously untreated patients with chronic myelocytic leucemia, single injections of this radioisotope produced clinical and hematologic remissions. One of these patients is still in remission after eleven months. However, no significant clinical response was produced by the isotope in two patients with chronic myelocytic leucemia who no longer responded to conventional irradiation therapy. One patient with an acute myelocytic leucemia failed to respond. One patient with a subacute myelocytic leucemia had clinical and hematologic remissions of about two months after each of two injections. However, this latter case required frequent transfusions and an osteomyelitis of the femur failed to heal in spite of chemotherapy and surgery.

Three patients with chronic lymphocytic leucemia treated with less than 30 millicuries were not benefited. One aged male previously insensitive to nitrogen mustard and needing massive transfusions responded with a decrease in lymph node enlargement and splenomegaly, an increase in subjective sense of well being as well as a depression of the white count for about two months. Two patients with acute lymphocytic leucemia were treated with 70 and 60 millicuries, respectively. One had a temporary and incomplete remission; in the other, a definite clinical and hematologic remission of approximately eight weeks occurred.

Two patients with polycythemia rubra vera were treated with radioarsenic. A relatively brief remission was produced in one of these patients who was given a dose of 45 millicuries. The other patient received essentially a trace

dose Four patients with Hodgkin's disease received less than 13 millicuries of As^{76} each The clinical effect of the isotope on the course of these four patients was essentially insignificant Likewise, two patients with multiple myeloma failed to respond favorably to this radioisotope

The huge liver of a patient with metastases from a carcinoma of the stomach decreased about 5 cm in size following 80 millicuries of As^{76} in two doses Nevertheless, his clinical condition continued to deteriorate and he died within two weeks

127 A METHOD OF FREQUENT ESTIMATIONS OF CIRCULATING PLASMA VOLUME WITH ERYTHROCYTE COUNTS, ADAPTABLE TO LONG-CONTINUED OBSERVATIONS

HENRY E HAMILTON, M D (BY INVITATION), RAYMOND F SHEETS, M D (BY INVITATION), AND ELMER L DEGOWIN, M D, IOWA CITY, IOWA

The fluctuations in plasma volume may be studied at will over a period of many days with little inconvenience to the subject An initial measurement of the plasma volume by Evans blue dye (T-1824) and a coincident erythrocyte count are correlated with subsequent changes in the peripheral erythrocyte counts The proof depends upon the demonstration of the following facts (1) With careful attention to the usual technique for counting erythrocytes, values were obtained with a standard deviation of $\pm 68,000$ cells per cubic millimeter (2) Erythrocyte counts on the peripheral blood of normal active adults were found to vary from day to day, sometimes with a range of 1,000,000 cells per cubic millimeter The variation frequently occurred in cycles of two or three days (3) In subjects who had received transfusions of blood of heterologous group, the unagglutinable cell counts (donor's blood) varied coincidentally with those of the recipient, in the same direction and in approximately the same magnitude (4) When estimates of the plasma volume were made from the cell count some days after the original measurement by the dye method, they were found to correspond with a second measurement by the dye within ± 5 per cent

The method consists of an initial measurement of the circulating plasma volume by Evans blue dye coincident with an erythrocyte count The fluctuations in erythrocyte counts thereafter can be observed over a period of many days and the plasma volume calculated from any single observation by the equation

$$PV_2 = \frac{C_1 \times PV_1}{C_2}$$

where PV_2 is the calculated plasma volume in milliliters, PV_1 is the plasma volume in milliliters measured by the dye method, C_1 is the erythrocyte count in millions per cubic millimeter in the peripheral blood taken at the time when PV_1 was determined, and C_2 the erythrocyte count in millions per cubic millimeter at the time of the calculation

The method assumes (1) that the total number of red cells in the body remains the same and (2) that the hematocrit of the peripheral blood bears a constant relationship to the total body hematocrit

This procedure has been employed to follow the daily fluctuations in plasma volume during normal activity, during hydration and dehydration, and in recipients undergoing blood transfusion The same method is applicable to the study of many problems in the clinic Daily erythrocyte counts alone, when accurately performed, should serve as an indication of variations in plasma

volume in patients who are not losing blood and whose bone marrow is functioning normally

128 THE INFLUENCE OF RUTIN BENADRYL AND PROTAMINE ON EXPERIMENTAL PURPURA IN THE GUINEA PIG

FRANK H BELFUS, M D (BY INVITATION) AND FREDERICK W MADISON M D
MILWAUKEE WIS

Thrombocytopenic purpura was produced in eighty guinea pigs by the use of antiplatelet serum according to the method of Bedson. The purpuric animals were divided into four groups of twenty each. One group served as control and received only the previously prepared antiplatelet serum. A second group received rutin, a third group Benadryl and a fourth group Protamine simultaneously with the serum. Serial determinations of erythrocytes, platelets and petechiae were made over a twenty four hour period following the administration of the serum and the drug. The petechial responses were measured by means of a negative pressure apparatus and the petechiae counted within a standard area.

The animals of the control group which received only antiplatelet serum exhibited a slight drop in erythrocytes, a marked fall in the platelets and a sharp rise in petechial formation. The greatest number of petechiae occurred within six hours after the injection of antiplatelet serum which was well in advance of the maximum fall of platelets. When the platelets had reached their lowest numbers the petechial response had subsided.

The second group of animals were given rutin in repeated injections of 10 mg per kilogram of body weight in addition to the initial dose of antiplatelet serum. These animals exhibited the same trend in platelet depression as the control group. The petechial response of the rutin group was approximately 60 per cent less than that of the control group.

The third group of animals were given the antihistamine drug, Benadryl in doses of 10 mg per kilogram in addition to the antiplatelet serum and a similar platelet depression occurred. However, the petechial response showed reduction of about 40 per cent as compared with the control animals.

The fourth group of animals received protamine in repeated doses of 2 mg per kilogram in addition to antiplatelet serum. Again the platelet depression followed the usual pattern but the petechial response was markedly diminished. Almost 90 per cent fewer petechiae were produced than in the control group.

Each of the drugs tested therefore showed ability to alter the vascular response (in varying degrees) under the conditions of this experiment but none showed any effect on the thrombocytopenia.

129 EFFECT OF VITAMIN K ON DICUMAROL INDUCED HYPOPROTHROMBINEMIA IN RATS

E J BOYD M D (BY INVITATION) AND E D WARNER, M D
IOWA CITY IOWA

Most of the reports dealing with the effect of vitamin K on Dicumarol induced hypoprothrombinemia have been based on one or another of the one stage methods for prothrombin estimation. It has been shown that these methods depend not only on the concentration of prothrombin but also on the rate of conversion of prothrombin to thrombin. The two stage method of prothrombin determination separates the conversion phase from the clotting phase and thereby largely eliminates the rate of conversion of prothrombin to

thrombin as a factor in prothrombin measurement. For this reason, it seemed pertinent to study the effect of vitamin K on Dicumarol-induced hypoprothrombinemia by the two stage prothrombin method.

Albino rats were made hypoprothrombinemic by the administration of Dicumarol. To control the dosage better, the Dicumarol was given by stomach tube. Vitamin K was given in daily doses as menadione in oil by stomach tube, or as Hykinone by intraperitoneal injection. Doses as large as 50 mg of menadione and 4 cc Hykinone (1 cc equivalent to 25 mg menadione) per day were used. The data obtained by the two-stage prothrombin determination indicate that (1) rats tend to develop a tolerance to Dicumarol, (2) massive doses of vitamin K in the form of menadione, or Hykinone, have no definite effect on Dicumarol-induced hypoprothrombinemia in rats, from either the prophylactic or the curative standpoint.

130 THE USE OF INTRAMUSCULAR HEPARIN FOR ANTICOAGULANT THERAPY

GEZA DE TAKATS, M D, AND EVELYN M ROGERS, R N (By Invitation)
CHICAGO, ILL

In a series of 100 patients, subcutaneous and intramuscular injections of heparin were given to maintain a prolonged coagulation time for prophylactic or therapeutic purposes. The solutions used were 1 and 10 per cent aqueous heparin and a preparation which uses gelatin dextrose and vasoconstrictors to delay absorption.

After considerable trial with various dosage and timing, the following tentative schedule has been developed.

The patient first is given 1 cc of 1 per cent heparin intravenously to determine his heparin tolerance. The coagulation time is determined before and only once, ten minutes, after the injection. If there is a 100 per cent increase in coagulation time following the injection, he is regarded as having a normal response and is given 5 cc of heparin intravenously. One hour following this injection, which usually raises coagulation time to about 15 minutes by the venous method, the first intramuscular injection is given with the heparin glycerin mixture. In from twelve to sixteen hours this is repeated, the coagulation time by the capillary method is always done before the next injection to avoid a stepladder type of effect.

There has been no reaction to the intramuscular injections either in the form of hematoma or induration, and the coagulation times have shown a stable level which was hitherto impossible to obtain even by the continuous intravenous drip.

131 THROMBOCYTOPENIA SECONDARY TO INFECTIOUS MONONUCLEOSIS

RICHARD M. ANGLE, M D (By Invitation), AND HOWARD L. ALT, M D
CHICAGO, ILL

Thrombocytopenic purpura is a rare complication of infectious mononucleosis. A report is made of a 19-year-old white female student nurse who developed petechiae, ecchymoses, and menorrhagia during the course of infectious mononucleosis. The platelet count fell to 10,000 per cubic millimeter. Spontaneous recovery accompanied convalescence from the infectious mononucleosis. The patient has remained well with a normal platelet count and no further bleeding episodes.

A review of the literature reveals only two identical cases. In two other reported instances there appeared to be a pre-existing bleeding diathesis which was aggravated by the infectious mononucleosis. In other possible cases the diagnosis of infectious mononucleosis was never definitely established or in sufficient details were reported to permit comparison.

Although the platelet count is said to be normal in infectious mononucleosis, no report of serial counts in this disease was found. We have determined the number of platelets at frequent intervals in seven consecutive cases of infectious mononucleosis. In five of the seven patients the platelet count was below the lower limit of normal during the first week of the disease. In one case the platelets were just above the lower limit of normal, and in another, initial counts were not made until the second week of the disease. During the second week of the illness a mild thrombocytosis ranging from one and one half to five times the lowest count occurred in six patients. This was followed by a gradual return to normal values. The case studied first in the second week of the disease, showed a mild thrombocytosis which subsequently returned to normal. In four of the seven patients the spleen was palpable and abnormal liver function was present in all.

The possibility that thrombocytopenic purpura in infectious mononucleosis may result from a similar but exaggerated depression of the blood platelets is suggested.

The possible roles of infection and hypersplenism as a cause of the thrombocytopenia will be discussed.

132 THE EFFECT OF DIGITALIS ON THE COAGULABILITY OF BLOOD

JOHN HASLOP FLINN M.D. ROCHESTER MINN.

(INTRODUCED BY HOWARD B. BURCHELL M.D.)

The high incidence of thromboembolic complications in cases of congestive heart failure is generally recognized. In the past five years several reports have appeared in the literature which implicated digitalis as a contributing factor to intravascular coagulation of the blood. Other reports have subsequently appeared which seem to deny this implication. The present study was undertaken in an attempt to determine whether certain cardiac glycosides do change the coagulability of the blood and if so how these changes can be measured. Because of the controversial reports it seemed evident that an investigation which would include both animal and clinical research and would consist of a study of blood coagulation by several methods before and during digitalization was indicated.

The problem was first investigated in the physiology laboratories of the Mayo Clinic and rabbits and rats were used. The study was completed in the Worrall Hospital, Rochester, Minn. with patients on the cardiac services of the Mayo Clinic. Studies of coagulation included the Lee White coagulation time, prothrombin times of whole and diluted plasma and heparin retarded coagulation time.

Results of the investigation show that lanatosid C and digitoxin administered to normal rabbits and rats in doses simulating therapeutic use of the drugs have a definite accelerating effect upon coagulation of the blood as measured by the Lee White coagulation time tests. In rabbits the *in vitro* heparin retarded coagulation time test showed a similar effect on coagulation of the blood. No effect was noted on the prothrombin time of whole or diluted plasma. In the normal rabbit relatively large doses of lanatosid C appear to have an antagonistic effect to Dicumarol.

The blood of clinically digitalized patients was not changed from that of normal subjects as measured by the Lee-White coagulation time tests or by the prothrombin time studies of whole or diluted plasma. However, digitalization appeared to diminish the anticoagulant effect of heparin in the human being.

These results seem to indicate that digitals may be a factor in promoting intravascular coagulation of blood.

EDITORIAL ANNOUNCEMENT

On January 1, 1949, Doctor Clayton G. Loosh will become Editor of the JOURNAL OF LABORATORY AND CLINICAL MEDICINE. After that date, all correspondence relating to editorial matters should be addressed to him at the University of Chicago, Department of Medicine.

For the past two years, this Journal has been published under the editorial direction of the Central Society for Clinical Research. It seems appropriate now to announce the way in which the Editor and the members of the Board of Editors are selected. The Editor is appointed by the Council of the Central Society for a term of three years, he may be appointed for a second three-year term, but may not serve consecutively for longer than six years. When the Editorship is to be vacated for any reason, the Board of Editors recommends a successor from the Society's membership to the Council. The Council may accept this recommendation or may make its own appointment. Doctor Loosh represents the unanimous and enthusiastic choice of the Council, the Board of Editors, and the retiring Editor.

Members of the Board of Editors are appointed by the Editor to serve for a three-year period. Each member is eligible for reappointment to a second, but not to a third consecutive term. Appointments are staggered so that four or five terminate at the end of each calendar year. Members of the Board are selected from among the active, emeritus, and adjunct membership of the Central Society for Clinical Research.

The retiring Editor wishes to express publicly his sincere appreciation first, to all members of the various Editorial Boards who have served with him during the past five years, second, to the many clinical investigators who have supported the Journal by sending their manuscripts to it, and third, to the editorial department of The C. V. Mosby Company for constant, wholehearted cooperation.

SUBJECT INDEX

A

- Acetylcholine, sensitivity of heart to, effects of acute hypoxia on, 1495
- Acidity, gastric, response during administration of protein hydrolysates, 1627
- variations in stimulated and nonstimulated stomach, diagnostic and therapeutic implications of, 1626
- Actinomycosis, penicillin in treatment of, 521
- Addisonian pernicious anemia, effect of vitamin B₁₂ on hematopoietic and nervous systems in, 1646
- Adrenal cortex, role of, in urate metabolism and in gout, 1473
- Adrenalectomy and adrenal cortical hormone, influence of, on hypoferrinemia and other blood changes associated with injection of turpentine, 532
- Adrenalin in normal and hypertensive patients, effects of, in relation to mechanism of sustained pressure elevations, 332
- Albumin and globulin in serum or plasma, determination of, a rapid clinical method for the accurate, 367
- egg, increase of complement units by, 239
- globulin, and hemoglobin contents in human, micromethod for determination of, 1440
- human, clinical method for determination of, by means of a precipitin reaction, 1052
- Alcoholic fatty liver, observations on, with use of interval needle biopsy and liver function tests, 555
- Allergy, food, acute torticollis due to, 1614
- Alloxan, diabetic response of weanling rats to intravenous doses of, 1161
- Amino acid preparation, a new lyophilized, determination of nitrogen balance index of, in protein deficient patients, 280
- Aminopterin, acute leucemia induced by, changes in blood and bone marrow in, 1481
- treatment of acute leucemia with, 1642

- Folic acid antagonist treatment of chronic leucemia with, 1643
- metabolism studies, 1271
- treatment of acute leucemias with analogues of, 1641
- Food allergy, acute torticollis due to, 1614

4 Amino pteroylglutamic acid treatment of acute leucemia with 1642
Frozen sections preparation of, for use in chemosurgical technique for microscopically controlled excision of cancer, 392

G

Gantrosan and penicillin prevention of bacteremia following tooth extraction with 1461
Gastric acidity response during intravenous administration of protein hydrolyates 1627
secretion effect of enterogastrone concentrations on 1622
twelve hour nocturnal, comparison of in uncomplicated duodenal ulcer before and after healing 1623
secretory response to histamine incidence of symptoms and in patients with and without chronic gastritis 1624
Globin and porphyrin metabolism made with C¹⁴ and N¹⁵ 1478
Glomerular filtration and effective renal plasma flow effects of cold pressor test on 430
Glucose tubular reabsorption of in diabetic patients effect of insulin on 1616
Glycine administered by vein efficacy and safety of 1555
Glycosuria simulated by the administration of ascorbic acid occurrence and differentiation 1471
Gout exophthalmos, radioiodine tracers in effect of varying dose of iodine on behavior of 1615
Gold compounds in treatment of arthritis metabolism toxicity and manner of action of 1381
distribution of in animal body in relation to arthritis 1133
toxicity in rats effect of BAL on 1024
Gout role of adrenal cortex in 1473

H

Haverhill fever bacteriologic diagnosis 1608
Hayem's solution for red blood counts methods to increase accuracy in use of 1180
serum flocculation reaction with routine use of 1629
Heart disease congenital intravenous catheterization of heart in diagnosis of 1439
emetine therapy in presence of 1457
intravenous catheterization of in diagnosis of congenital heart disease 1489
sensitivity of to acetylcholine effects of acute hypoxia on 1495
Hemagglutinin test cold by a slide method 1447
Hematopoietic tissues radioarsenic (As⁶) in treatment of leucemia and allied disorders of 1649
Hemoglobin determination of as pyridine hemochromogen 1638
estimation crystalline hemin solutions as permanent standards for 783
oxygen saturation of recording of by a whole blood oximeter 1637

Hemolytic diseases plasma catalase in 487
transfusion reactions intragroup incompatibility with respect to H_r blood factors as a cause of minor 98a
Hemophilia current theories and successful management in traumatic and surgical crises 708
Hemouderin sternal marrow 81
Heparin and dicumarol comparative action of on the in vivo clot experimental study of 721
commercial effect of on platelet count, 1410
effect of on platelets in vivo 1424
use of intramuscular for anticoagulant therapy 1652
Hepatic cirrhosis needle biopsy of liver in experiences with 1627
qualitative and quantitative definition of cirrhosis and anions in 1545
dysfunction in infectious mononucleosis review of literature 1258
Hepatitis infectious inadvertently transmitted with therapeutic malaria 998
urine in acute antidiuretic activity of 1476
Heterophile antibodies demonstration of in cerebrospinal fluid in infectious mononucleosis 1204
Hetrazan pharmacodynamic properties of 216
Histamine administration during pregnancy clinical observations on 1601
antagonists 319
gastric secretory response to incidence of symptoms and in patients with and without chronic gastritis 1624
test for presence of hypertensive diencephalic syndrome using, 1470
treatment of retrobulbar neuritis 1611
Histoplasmosis complement fixation test for yeast phase antigens in 811 1207
Hodgkin's disease sternal marrow studies in 1640
syndrome studies in 1002
Hookworm need of differentiation of trichostrongylus infection in human beings from 869
Hormonal influence in experimental anuria, 1489
H_r blood factors intragroup incompatibility with respect to as a cause of minor hemolytic transfusion reactions 985
Hydrolysis of conjugated urinary estrogens, comparison of methods used for 207
Hyperemia reactive failure of antihistamine drugs to reduce 1609
Hyperglycemia effect of on clearances of inulin and paraaminohippuric acid 1617
Hypertension arterioles of skin in 1436
arteriovenous nicking in long term study of 1486
cholesterol tolerance tests in 1618
insulin tolerance in 1487
new method of studying 1483
pulmonary in chronic hypertrophic pulmonary emphysema 1433

Hypertension—Cont'd

- thiocyanate content of saliva in, before and after ingestion of drug, 772
- Hypertensive diencephalic syndrome, test for presence of, using histamine, 1470
- Hyperthyroidism, movement test in, electrocardiographic response to, 1500
- surgical management of, medical and metabolic factors in, 1618
- Hypertrophic pulmonary emphysema, pulmonary hypertension in chronic, 1453
- Hypoparathyremia, frequency and significance of, studies in serum proteins, 1276
- Hypoferrinemia and other blood changes associated with injection of turpentine, influence of adrenalectomy and of adrenal cortical hormone on, 532
- Hypoprotrothrombinemia, diuretic induced, in rats, effect of vitamin K on, 1431, 1651
- idiopathic (familial), 542
- Hypospary apparatus, administration of penicillin and streptomycin by means of, 505
- Hypoxia, acute, effects of, on sensitivity of heart to acetylcholine, 1495

- Lecithin, sensitivity of, variations in different lots of purified, 1220
- Letthal procedures, effect of various, and thermal injury on capillaries, 497
- Leucemia, acute, induced by aminopterin, changes in blood and bone marrow in, 1451
- effect of methine on, further studies on, 1647
- ridionism (A.S.) in treatment of 1649
- treatment of acute, with aminopterin (1-aminopteroylglutamic acid), 1642
- with analogues of folic acid, 1641
- chronic with a folic acid antagonist, 1643
- Life span of sickle cell and the pathogenesis of sickle cell anemia, 975
- Ligation of pancreatic ducts, effect of and of pancreatotomy after duct ligation on serum lipase, 933
- Lipids, suggestion of various, influence of upon the thymol turbidity test, 1640
- Liver, alcoholic fatty, observations on with interval needle biopsy and liver function tests, 555

Liver—Cont'd

- antipermeous anion factor of and pteroylglutamic acid for hemopoiesis a estimate of both 164
- cirrhosis of blood and bone marrow in 1045
- life expectancy of patients with effect of choline methionine, and low fat diet on 1123
- diarrheal serum choline factor determinations in 1475
- extract and vitamin B₁₂ effect of on mucous membrane lesions of microcytic anemia 1019
- function bromsulphalein test of importance of rate of dye removal in 445
- serum albumin globulin ratio cephalin cholesterol flocculation and thymol turbidity tests for a comparative study 462
- its in observations on alcoholic fatty liver 355
- needle biopsy of in hepatic cirrhosis experience with 162
- portal cirrhosis of chemical and functional study 1455
- structural and functional alteration of relation between 435
- lower nephron nephrosis management and clinical course of 1806
- lung action of pilocarpine on in normal and asthmatic subject 385
- lymph collection of from liver small intestine or thoracic duct of rat technique for 1349
- Lymphadenitis acute bacterial pathogenesis of 1435
- Lymphoblastoma cutis and scleroderma pyriminobenzol acid therapy in 1462
- Lymphogranulomatous patients electrophoretic study of blood serum from 624
- Lymphoid cell extracts antibody content of determination of 1563
- Lysophilized amino acid preparation a new determination of nitrogen balance index of in protein deficient patients 280

M

- Macrocolorimeter Evelyn microcolorimeter for 1594
- Microcytic anemia mucous membrane lesions of effect of liver extract and vitamin B on 1019
- Malaria sporozoite induced virus incidence of tube positive tests for syphilis and 747
- therapeutic infectious hepatitis inadvertently transmitted with 998
- use of Lithiodium virus preserved by freezing in medium 1594
- Malignant hypertensive persons effects of bacterial pyrogens on 1469
- Mammalian striated myofibril preparation and properties of 1612
- Mandelamine (methenamine mandelate) absorption distribution and renal excretion of 1704

- Measurement of surface temperature of body thermocouples for improved mounting for 1044
- Megalocyte and hemolytic syndrome of pernicious anemia life span of 1064
- Mercurial diuretic for subcutaneous injection experiences with 1635
- Mercure bichloride for biologic studies factors in use of with especial reference to blood counts 1094
- Mescaline hallucinations effect of acemate in 1297
- Metabolic studies on puppies infused with fat emulsions 150
- Metabolic globulin and porphyrin made with C¹⁴ and N¹⁵ 1475
- protein kinases of 257-69
- study folie acid 171
- Methenamine mandelate absorption distribution and renal excretion of 104
- Methionine choline and low fat diet effect of on life expectancy of patients with cirrhosis of liver 1123
- Methylol (B-chloroethyl) amine hydrochloride chemical observations with 1648
- Micro and macroelectrophoretic analysis of human and rat serum a comparative study of 50
- Microdip for the Evelyn microcolorimeter 1594
- Microbiological protein factor concentrate activity of in pernicious anemia, 860
- Microcolorimetric determination of sodium in human biologic fluids 246
- Micrometer burette a Scholander of simple construction 1593
- Micromethod for determination of human albumin globulin and hemoglobin contents 1440
- of serum streptomyces levels 896
- Microorganisms pathogenic use of splenic infusion as a base for growing certain 1035
- Microtechniques for identification of cultures quick 1334-1338
- Molybdenum iron complex anemia of pregnancy treated with 1641
- Mononucleosis infectious hepatic dysfunction in review of literature 1558
- heterophylous antibodies in cerebrospinal fluid in 1204
- thrombocytopenia secondary to 1552
- Mycetis following administration of neocarsphenamine 1165
- Myocardial infarction dicumarol in experimental 981
- extremity and precordial leads in diagnosis of acute a comparative evaluation of 1500
- observations of 100 patients with who survived up to six years 1488
- Myofibrils mammalian striated preparation and properties of 1612

N

- Needle biopsy of liver in hepatic cirrhosis experiences with 1627
- Neorsphenamine myelitis following administration of 1165

- Neohetramine, a new antihistaminic agent, experimental and clinical studies, 565
- Nephron nephrosis, management and clinical course of lower, 1606
nature of the altered renal function in lower, 1468
- Nephrosis, edema in, relief of, by plasma albumin and gelatin infusions, 1491
- Neuritis, retrobulbar, treatment with histamine, 1611
- Newborn, erythroblastosis fetalis in, maternal isoimmunization without evidence of clinical, 526
- Nicotinic acid amide, effect of, on experimental tuberculosis of white mice, 1249
- Nitrogen balance index, determination of, in a new lyophilized amino acid preparation in protein deficient patients, 280
studies, comparative, of oral protein derivatives and natural protein in protein deficient patients, 1634
mustard and X irradiation, effect of, on blood coagulation, 1566
inhibitory effect of, on development of humoral antibodies, cutaneous hypersensitiveness and vascular lesions in rabbits following injections of horse serum, 1463
therapy, 1002
- Normoblasts in peripheral blood, appearance of, in patients with pulmonary embolism, 1502
- Nutrition and experimental diabetes, 1161
effect on tumor response in Rous chicken sarcoma, 1139
intravenous, fat emulsions for, 175
improved techniques for preparation of, 153
parenteral, 143, 153, 163, 175, 1503
- Nutritional status and infection response, 47
- O
- 1 Diethylcarbamiyl 4 methylpiperazine hydrochloride, pharmacodynamic properties of, 216
- Ossilograph, direct writing, for recording data obtained by method of cardiac catheterization, 1499
- Oximeter, whole blood, recording of oxygen saturation of hemoglobin by, 1637
- Oxyhemograph, studies on cardiorespiratory function with, 1454
- Oxyquinoline drugs, influence of, on growth of *Endamoeba histolytica*, as measured in blood iodine levels of man, 1632
- P
- Palpitation, 1487
- Pancreatic calcification, diffuse, with diabetes mellitus, 1619
ducts, effect of ligation of, and of pancreaticectomy after duct ligation on serum lipase, 833
function, studies on, 1047
- Para aminobenzoic acid, effect of, on metabolism and excretion of salicylate, 1393
therapy in scleroderma and lymphomatous cutis, 1462
- Parenteral nutrition, 143, 153, 163, 175, 1503
- Paroxysmal tachycardia, low nodal, benefited by cardiac sympathectomy, 1493
- Pathogenesis of acute bacterial lymphadenitis, 1458
- Pathologic specimens, imbedding of, in transparent plastic, 1311
- Penicillin and gentrosan, prevention of bacteremia following tooth extraction with, 1461
and streptomycin, administration of, by means of hypodermic apparatus (jet injection), absorption, toxicity and stability, 805
in isolation of poliomyelitis virus from fecal specimens, 1402
in treatment of actinomycosis, 521
levels, high blood, achieved with caronamide, role of, in penetrating the blood brain barrier, 933
plasma protein fractions in action and transport of, 1608
procaine, therapeutic efficiency and comparative study of absorption, 1232
rectal absorption of, 135
response of bacterial populations to the action of, 417
- Pepsin, purification of diphtheria and tetanus antitoxin by use of, 757
- Peptic ulcer, bleeding, 1624
- Peripheral circulation in man, effects of dihydroergocornine on, 1497
- Pernicious anemia, activity of microbial animal protein factor concentrates in, 860
cholinesterase activity of blood in, 149
life span of the megalocyte and the hemolytic syndrome of, 1068
- Pharmacology of heparin, 216
- Phenol production, effect of phthalylsulfathiazole and streptomycin on, 840
retention, relation of, to uremia, 845
- Phospholipids, high vitamin A intake and blood levels of, 67
- Phthalylsulfathiazole and streptomycin, effect of, on phenol production, 840
- Pilocarpin, action of, on lungs in normal and asthmatic subjects, 585
- Pituitary adrenocorticotrophic hormone, production of temporary diabetes mellitus with, 651
dwarfism, anterior pituitary extract in treatment of, 1615
- Plasma, albumin, and globulin in determination of, a rapid clinical method for the accurate, 367
catalase in hemolytic diseases, 487
in normal adults, method for determination of, and values obtained, 451
concentrations of caronamide, 297
corticosteroids in, methods for chemical determination of, 1326
defect in patients whose bleeding is temporarily controlled by protamine

Plasma—Cont'd

- sulfate or toluidine blue 1400
- protein fractions role of in action and transport of penicillin 1408
- of man effect of oral administration of casein hydrolysate on total circulating 453
- studies in children with rheumatic fever 1490
- vitamin A alcohol influence on endogenous and nutritional factors upon 1631
- volume circulating method of frequent estimations of with erythrocyte counts 1650
- Plasmodium vivax preserved by freezing use of in inducing malarin 1579
- Plastic transparent imbedding of pathological specimens in 1311
- Platelet count effect of commercial heparin on 1410
- Platelets in vivo effect of heparin on 1424
- Plethysmograph a compensating for measuring blood flow in human extremities 101
- Pneumococcus hyaluronidase in serum of normal human beings and patients with pneumococcal pneumonia anti-hyaluronidase antagonistic to 919
- Pneumonia and influenza 30
- serologic studies of after outbreak of influenza B 32
- bacteremia pneumococcal rise of titer in 919
- Poisoning ethylene glycol clinical and pathologic study 573
- Poisons common steam volatile organic systematic qualitative analysis of biologic materials for 371
- Polyomyelitis virus isolation of from fecal specimens use of penicillin and streptomycin in 140
- Polyethylene tubing venous catheterization with 159
- Porphobilinogen tests on 1000 patients in search for false positive reactions 1254
- Portal cirrhosis of liver clinical and functional study 1470
- Precipitin reaction determination of human albumin by means of clinical method for 1002
- Pregnancy anemia of treated with molybdenum iron complex 1641
- blood pressure maintenance in normal and toxemic using tetraethylammonium chloride evaluation of neurologic and humoral factors in 1466
- histamine administration during clinical observations on 1601
- Pregnandiol colorimetric method for determination of a new 251
- in urine quantitative colorimetric estimation of simplified technique for 356
- Pregnant women Rh immunized anti A and anti B isoagglutinin titers in 1089

Pregnant women—Cont'd

- urinary volume of effect of sedatives on 1460
- Incident's address Central Society for Clinical Research October 29 1948 1458
- Intracerebral elevations mechanism of sustained effects of adrenalin in normal and hypertensive patients in relation to 332
- Procaine penicillin therapeutic efficiency and a comparative study of absorption 1232
- Lipidolipid and cholesterol, effect of feeding on blood cholesterol and arterial intima in rat 1029
- Protamine rutin and benadryl, influence of on experimental purpura in the guinea pig 1651
- acute bleeding temporarily controlled by plasma defect in 1450
- Protein hydrolysates gastric acidity response during intravenous administration of 1627
- metabolism dynamics of 257 269
- requirements of adult dogs studies on the minimum 462
- Infantile patients comparative nitrogen balance studies of oral protein derivatives and natural protein in 1634
- Prothrombin activity concentration of labile factor of prothrombin complex in human dog and rabbit blood significance of in determination of 919
- Pseudohypoparathyroidism 1620
- Pittuitary virus acquired resistance of to sulfadiazine and effects of chemical antagonists on sulfonamide reactivity 1241
- Psychoneuroses premature calcification of costal cartilages associated with 1621
- Psychosomatic problems in a private practice 1621
- Pteroylglutamic acid and pteroylglutamic acid intravenous administration of in folic acid metabolism studies 1271
- antagonists of use of in controlling Rous chicken sarcoma 1144
- deficiency in swine effect of treatment with pteroylglutamic acid liver extract and protein 397
- for hematopoiesis and antipernicious anemia factor of liver essentiality of both 1647
- Pulmonary carcinoma "sputum cell study for as routine laboratory test 1558
- embolism peripheral blood of patients with appearance of normoblasts in 1503
- hypertension in chronic hypertrophic pulmonary emphysema 1453
- Purpura influence of rutin benadryl and protamine on experimental in the guinea pig 1651

Purpura—Cont'd

- thrombopenic, failure of direct blood transfusion to raise the platelet level, 1077
- Pyloric balance in ileus, 1625
- Pyribenzamine and benadryl, comparison of toxic manifestations produced by, 595
- Pyridine hemochromogen, determination of hemoglobin as, 1638

Q

- Quantitative complement fixation test for syphilis, method for determination of titers between 10 and 100 m, 383
- Ischemia in limbs of animals, apparatus for producing, 1450

R

- Radioactive isotopes from biologic tissue, recovery and estimation of, 1169
- Radioimmunity induced is stilbene, tissue distribution of, 635
- Radionuemic (As^{76}) in treatment of leukemia and allied disorders of the hematopoietic tissues, 1649
- Radioiodine tracers in exophthalmic goiter, effect of varying dose of iodine on the behavior of, 1615
- Reactive hyperemia, failure of antihistaminic drugs to reduce, 1609
- Recording electrocardiographic leads, multiple and special, devices for rapid, 118
- Rectal absorption of penicillin, 135
- Red blood cells, destruction of, studies on, 1197
 - counts, Hayem's solution for, methods to increase accuracy in use of, 1180
- Renal function, altered, nature of, in lower nephron nephrosis, 1468
 - hypertension, effect of desoxycorticosterone acetate and propylene glycol in experimental, 1483
- Resin utilized kidney 841
- Respiratory and circulatory systems, relation of tobacco smoking to diseases of, 1497
- Retinal arteriovenous nicking, 1486
- Retinobulbar neuritis, treatment with histamine 1611
- Rh antibodies, detection and identification of, use of preserved erythrocytes for, 1177
 - studies on, 1353, 1361, 1369
 - antisera analysis of a zone phenomenon in, by splitting the serum into two fractions by means of dialysis, 1353
- Rh immunized pregnant women, anti A and anti B isogglutinin titers in, 1089
- Rheumatic fever, plasma protein studies in children with, 1490
 - renal excretion of silchylate during treatment of acute, 1636
- Rice diet, dangers from use of, 1468

- Rous chicken sarcoma, effect of nutrition on tumor response in, 1139
 - use of antagonists of pteroylglutamic acid in controlling, 1144
- Rutin, benadryl, and protamine, influence of on experimental purpura in guinea pig, 1651
 - effect of, upon resorptive toxicity of certain drugs, 1464

S

- Silchylate, metabolism and excretion of, effect of para aminobenzoic acid on, 1393
 - renal excretion of, during treatment of acute rheumatic fever, 1636
- Silva, thioxy urate content of, in normal and hypertensive subjects before and after ingestion of the drug, 772
- Salmonella bleedum, occurrence of, in Louisiana, 1155
- Sarcoma, Rous chicken, effect of antagonists of pteroylglutamic acid in controlling, 1144
 - of nutrition on tumor response in, 1139
- Scholander micrometer burette of simple construction, 1193
- Scleroderma and lymphoblastoma cutis, para aminobenzoic acid therapy in, 1462
- Screening method for blood glucose, 236
- Screw syringe, 1603
- Sedative drug, a new (3,3 diethyl 2,4 diisopropylidene) evaluation of, 602
- Sedatives, effect of, upon urinary volume of pregnant women, 1465
- Sedimentation rate technique, simplified, with combined chart and correction nomogram, 511
- Sensitivity, cistron bean, 1613
 - of lecithin, variations in different lots of purified, 1220
- Serologic studies, influenza and pneumomun during and after outbreak of influenza B, 32
 - in Boston during winter of 1945-1946, 15
- Serotonin crystallization of, 1606
- Serum, albumin and globulin in, determination of, a rapid chemical method for the accurate, 367
 - albumin globulin ratio, cephalin cholesterol flocculation test, and thymol turbidity test for liver function a comparative study, 662
 - antimetabolic cytotoxic, in arthritis, 765
 - failure of, 1289
 - calcium determination, rapid method for, 906
 - cholesterase determinations in liver disease, 1475
 - coagulation reaction, Weltmann further studies on, 618
 - dilution turbidity test in, in comparison with thymol turbidity and cephalin cholesterol flocculation test, 672

Serum—Cont d

- disease in rabbits, effect of sodium chloride upon 936
- flocculation reaction with Hygeum's solution routine use of 1629
- human and rat micro and macroelectrophoretic analysis of comparative study, 75
- hypase, effect of ligation of pancreatic ducts and of pancreatectomy after duct ligation on 833
- simplified method for determination of using aqueous tributyrin as substrate 1047
- proteins of blood dyscrasias electrophoretic analysis of 15-3
- studies in 36, 1246
- streptomycin levels micromethod for determination of 886
- Shock bacteria induced resulting from eruiling of muscle in dogs mechanism of 602
- Sickle cell anemia pathogenesis of and the life span of the sickle cell 975
- Sickling of red blood cell simple and rapid method for demonstrating use of reducing agents 1082
- Skin arterioles of in essential hypertension 1486
- Slide method of cold hemagglutinin test 1447
- Sodium diet the minimal its effect on blood pressure of ambulatory hypertensive subjects 148
- in human biologic fluids microcolorimetric determination of 240
- sulicylate effect of upon sodium chloride in rabbits 936
- Soybean phosphatides as emulsifiers for intravenous fat emulsions, 163
- Spectrophotometric determination of blood pH 881
- of urinary bilirubin 1189
- Splanchnectomy effect of on blood pressure and on cardiac and renal function 1455
- Splenic infusion, use of as base for growing certain pathogenic microorganisms 1037
- Sputum cell study for pulmonary carcinoma as routine laboratory test 1583
- Stain JSB a modified method of preparing 777
- Sternal marrow hemosiderin 81
- tubercles in Hodgkin's disease 1640
- Steroid diabetes associated with Cushing's syndrome and excretion of 17-hydroxycorticosterone (compound F) in urine metabolic studies 1442
- Stomach acidity variations in stimulated and nonstimulated diagnostic and therapeutic implications of 1646
- of cytologic diagnosis of 1637
- Stools streptomycin resistant bacteria in, development of in patients treated for tuberculosis 1460
- Streptomycin and penicillin administration of by means of hypodermic apparatus (jet injection) suboptimal toxicity and stability 805

Streptomycin and penicillin—Cont d

- in isolation of poliomyelitis virus from fecal specimens 1402
- and phthalylsulfathiazole, effect of, on phenol production 845
- experimental therapy of generalized torulosis in rats with 1159
- crum levels, micromethod for determination of 886
- therapy in United States Army hospitals 1
- Streptomycin resistant bacteria, development of in stools of patients treated for tuberculosis 1460
- Subtilin topical application of, to tuberculous lesions in man 190
- Succinate effect of in meclizine hallucinations 1297
- Sulfadiazine, acquired resistance of psittacosis virus to and effects of chemical antagonists on sulfonamide activity 1241
- Suppurative infection prolonged 1607
- Surface temperature of body thermocouples for measurement of, improved mounting for 1044
- Synthetic diets 1059
- Syphilis, false positive tests for incidence of in sporozoite induced vivax malaria 747
- in acute hemolytic anemia transient positive Wassermann test for 753
- quantitative complement fixation test for method for determination of titers between 10 and 100 in 383
- transient positive Wassermann test for, in acute hemolytic anemia 753
- Syringe screw 1603

T

- T wave of electrocardiogram factors influencing experimental study employing intracavitary and epicardial leads 1498
- Test, coagulation in erythroblastosis fetalis 191
- Titanium nitroxide purification of by use of pep in 157
- Tetraethylammonium chloride blood pressure maintenance in normal and toxemic pregnancy using evaluation of neurogenic and humoral factors in 1466
- effects of on blood flow in extremities of man 743
- Therapeutic malaria, infectious hepatitis inadvertently transmitted with 998
- Thermal trauma delayed death following, mechanism of 506
- Thermocouples for measurement of surface temperature of body improved mounting for 1044
- Thiocyanate content of saliva in normal and hypertensive subjects before and after ingestion of the drug 742
- Thionin a mercurial diuretic for subcutaneous injection experience with 1635
- 3,4-Dichloro-4-dioxopiperidine a new editive drug, evaluation of 602

- Thrombocytopenia secondary to infectious mononucleosis, 1652
- Thrombocytopenic purpura, coagulation defect in, 1479
- Thrombopenic purpura, failure of direct blood transfusion to raise the platelet level, 1077
- Thymol turbidity and cephalin cholesterol flocculation tests in serum, a dilution turbidity test in comparison with, 672
- influence of ingestion of various lipids upon, 1630
- test in various diseases, 565
- serum albumin globulin ratio, and cephalin cholesterol flocculation test for liver function, a comparative study, 662
- Tidal volume recorder for anesthetized dogs, 784
- Tissue distribution of radioantimony inhaled as stibine, 635
- Tobacco smoking, relation to diseases of respiratory and circulatory systems, 1497
- Toluidine blue, bleeding temporarily controlled by, plasma defect in, 1480
- Torticollis, acute, due to food allergy, 1614
- Torulosis generalized, experimental therapy of, in rats, with streptomycin, 1159
- Toxoplasma neutralizing antibodies, occurrence of, in various disease conditions, 87
- Trichostrongylus infection in human beings, need of differentiation from hook worm, 869
- Tripelennamine and beta dimethylaminoethyl benzhydryl ether hydrochloride, comparison of toxic manifestations produced by, 595
- Tuberculosis, experimental, effect of nicotinic acid amide on, in white mice, 1249
- Tuberculous lesions, topical application of subtilin to, 799
- Turpentine, blood changes associated with injection of, influence of adrenal ectomy and of adrenal cortical hormone on, 532
- 2 [α (2 dimethylaminoethoxy) α methylbenzyl] pyridine succinate, clinical and experimental results of, 319
- pharmacologic properties of, 325
- 2,3 Dithiopropanol, effect of, on gold toxicity in rats, 1024
- Typhoid carrier state, treatment of, 1150
- U
- Ulcerative colitis, duodenal substance in chronic, clinical evaluation of, 1633
- United States Army hospitals, streptomycin therapy in, 1
- Urate metabolism, role of adrenal cortex in, 1473
- U. on of phenol retention to, 845
- U effect of, on leucemia, further studies on, 1647
- Urinary bilirubin, spectrophotometric for determination of, 1189
- estrogens, hydrolysis of conjugated, comparison of methods used for, recovery from caronamide, 297
- sediment, erythrocytes in, identification and normal limits, 875
- volume of pregnant women, effect of, 1465
- Urine, bilirubin in, quantitative determination of, method for, 890
- corticosteroids in, methods for determination of, 1326
- excretion of 17 hydroxycorticosteroids (compound F) in, steroid diabetes associated with Cushing's syndrome and, metabolic studies, 1472
- in acute hepatitis, antidiuretic activity of, 1476
- pregnandiol in, quantitative colorimetric estimation of, simplified technique for, 356
- V
- Vaccination against influenza, results of, during epidemic of 1947, 789
- Venous catheterization with polyethylene tubing, 1597
- Ventricular irregularities induced by sympathetic adrenal discharge and chloroform, 1438
- Vitamin A intake, high, and blood levels of cholesterol, phospholipids, carotene, and Vitamins C, A, and E, 67
- B₁₂ and liver extract, effect of, on mucous membrane lesions of macrocytic anemia, 1019
- effect of, on hematopoietic and nervous systems in Addisonian pernicious anemia, 1646
- in pernicious anemia and puerperal macrocytic anemia, 1477
- IK, effect of, on dicumarol induced hypoprothrombinemia in rats, 1431, 1651
- Volatile reducing substances (alcohol or ether) in blood and gases, determination of, using barium diphenylamine sulfonate as an indicator for chromic acid titration, 126
- W
- Wassermann test, transient positive, for syphilis in neutro hemolytic anemia, 753
- Water by vein, effect of, on the more severe complications of cardiovascular renal disease, 1467
- Weltmann serum coagulation reaction, further studies on, 618
- Whole blood oximeter, recording of oxygen saturation of hemoglobin in, 1637
- Y
- Yeast phase antigens in complement fixation test for histoplasmosis, 511, 1207
